**Abbreviations.**

The abbreviations used are GPCR, G protein coupled receptor;  $G\alpha_s$ ,  $\alpha$  subunit of the stimulatory G protein; GFP, green fluorescent protein;  $\beta$ AR,  $\beta$ -adrenergic receptor; GTP, guanosine triphosphate; ISO, isoproterenol; EEA1, early endosome antigen 1 protein; LAMP-1, lysosome associated membrane protein 1; CD, methyl- $\beta$ -cyclodextrin..

## **ABSTRACT**

Upon binding hormones or drugs, many G protein coupled receptors are internalized leading to receptor recycling, receptor desensitization and down-regulation. Much less understood is whether heterotrimeric G proteins also undergo agonist induced endocytosis. To investigate the intracellular trafficking of G $\alpha$ s, we developed a functional G $\alpha$ s-GFP fusion protein which can be visualized in living cells during signal transduction. C6 and MCF-7 cells expressing G $\alpha$ s-GFP were treated with 10 $\mu$ M isoproterenol, and trafficking was assessed with fluorescence microscopy. Upon isoproterenol stimulation, G $\alpha$ s-GFP was removed from the plasma membrane and internalized into vesicles. Vesicles containing G $\alpha$ s-GFP did not colocalize with markers for early endosomes or late endosomes/lysosomes, revealing that G $\alpha$ s does not traffic through common endocytic pathways. Furthermore, G $\alpha$ s-GFP did not colocalize with internalized  $\beta_2$ -adrenergic receptors, suggesting that G $\alpha$ s and receptor are removed from the plasma membrane by distinct endocytic pathways. Nonetheless, activated G $\alpha$ s-GFP did colocalize in vesicles labeled with fluorescent cholera toxin B, a lipid raft marker. Agonist significantly increased G $\alpha$ s protein in Triton X-100 insoluble membrane fractions, suggesting that G $\alpha$ s moves into lipid rafts/caveolae after activation. Disruption of rafts/caveolae by treatment with cyclodextrin prevented agonist induced internalization of G $\alpha$ s-GFP as did overexpression of a dominant negative dynamin. Taken together, these results suggest that receptor activated G $\alpha$ s moves into lipid rafts and is internalized from these membrane microdomains. It is suggested that agonist induced internalization of G $\alpha$ s plays a specific role in GPCR mediated signaling, and could enable G $\alpha$ s to traffic into the cellular interior to regulate effectors at multiple cellular sites.

G protein-coupled receptors (GPCRs) are the largest family of signaling molecules in the human genome. They couple to a diverse family of heterotrimeric G proteins that transduce chemical and sensory signals from the receptor to a variety of effectors, such as second messenger generating enzymes and ion channels. With respect to many GPCRs, agonist activation of receptors initiates processes in the cell which lead to receptor desensitization and internalization of the receptors by endocytosis.  $\beta$ -adrenergic receptors ( $\beta$ ARs) are prototypic GPCRs that have been studied in detail, particularly with respect to their agonist induced internalization (Claing et al., 2002). Upon agonist binding, the majority of GPCRs are trafficked into clathrin coated pits and internalized by endocytosis (Claing et al., 2002; von Zastrow, 2003). However, some receptors appear to be preferentially located and internalized through specialized lipid raft/caveolae microdomains of the plasma membrane (Claing et al., 2002; Nabi and Le, 2003), a process known as clathrin-independent endocytosis. The GTP binding protein dynamin plays an essential role in both types of receptor endocytosis by acting to liberate endocytic vesicles from the plasma membrane (Nichols, 2003). Lipid rafts and caveolae are plasma membrane microdomains enriched in cholesterol and glycolipids making them highly hydrophobic and insoluble to non-ionic detergents such as Triton X-100. Several signaling proteins including receptors, G proteins and effectors are enriched in both rafts and caveolae, suggesting that these microdomains are involved in G protein mediated signaling. Previous investigations have demonstrated that  $G_{\alpha s}$  is in fact targeted to and enriched in lipid rafts (Oh and Schnitzer, 2001). While agonist induced endocytosis of GPCRs is well characterized, relatively few studies have examined internalization of heterotrimeric G proteins.

$G_{\alpha s}$  is localized primarily at the plasma membrane, where it allosterically activates its classic effector, adenylyl cyclase, resulting in the production of cAMP during receptor signaling

**MOL MANUSCRIPT # 8342**

events. It has become increasingly clear that  $G\alpha_s$  is also located in other cellular compartments.  $G\alpha_s$  has been detected in endocytic vesicles obtained from liver (Van Dyke, 2004), it associates with tubulin and the microtubule cytoskeleton in neuronal cells (Roychowdhury et al., 1999; Sarma et al., 2003), and  $G\alpha_s$  is enriched in the trans Golgi network of rat pancreatic cells (Denker et al., 1996). Several studies have indicated other functional roles for  $G\alpha_s$  apart from activation of adenylyl cyclase, including regulation of apical transport in liver epithelia (Pimplikar and Simons, 1993), regulation of endosome fusions (Colombo et al., 1994) and controlling the trafficking and degradation of epidermal growth factor (EGF) receptors (Zheng et al., 2004). How  $G\alpha_s$  is trafficked to these cellular locations and the mechanism governing its association with these subcellular compartments remains unclear.

Several previous studies have indicated that  $G\alpha_s$  undergoes a redistribution from the plasma membrane to cytosol in response to agonist stimulation (Hynes et al., 2004b; Ransnas et al., 1989; Thiyagarajan et al., 2002; Wedegaertner and Bourne, 1994; Wedegaertner et al., 1996; Yu and Rasenick, 2002), however there are reports that have failed to see this redistribution (Huang et al., 1999; Jones et al., 1997). Recently, a fluorescent  $G\alpha_s$ -GFP fusion protein was developed by inserting green fluorescent protein into the internal sequence of  $G\alpha_s$ . This  $G\alpha_s$ -GFP fusion protein binds GTP in response to agonist, activates adenylyl cyclase, is appropriately expressed at the plasma membrane and exhibits identical trafficking and signaling behavior as the wild type  $G\alpha_s$  (Yu and Rasenick, 2002). During  $\beta$ AR stimulation, activated  $G\alpha_s$ -GFP rapidly dissociates from the plasma membrane in living cells (Yu and Rasenick, 2002). The mechanism controlling the release of  $G\alpha_s$  from the membrane is not yet known, but it has been suggested that activated  $G\alpha_s$  is depalmitoylated and then released from the membrane

**MOL MANUSCRIPT # 8342**

(Wedegaertner and Bourne, 1994). The ultimate redistribution and putative signaling of internalized  $G\alpha_s$  is poorly understood.

We have hypothesized that similar to receptor,  $G\alpha_s$  internalizes in response to agonist and associates with endocytic vesicles. Using real-time imaging of  $G\alpha_s$ -GFP during agonist stimulation, this report demonstrates that  $G\alpha_s$  dissociates from the plasma membrane and becomes internalized in vesicles. Internalized  $G\alpha_s$ -GFP containing vesicles were derived from lipid raft domains, but were not common to early or late endosomes. In addition, internalized  $G\alpha_s$ -GFP did not colocalize with  $\beta_2$ ARs in vesicles, suggesting that receptor and  $G\alpha_s$  traffic through distinct endocytic pathways. It is suggested that agonist induced internalization of activated  $G\alpha_s$  may regulate endocytic trafficking and play a specific role in GPCR mediated signaling, and could enable  $G\alpha_s$  to traffic into the cellular interior to interact with effectors at multiple cellular sites.

## **MATERIALS AND METHODS**

**Cell Culture and Transfections.** MCF-7 human breast adenocarcinoma and C6 rat glioma cell lines, both of which express endogenous  $\beta_2$ ARs, were used for these experiments. MCF-7 cells were cultured in DMEM (Invitrogen) containing 10% fetal bovine serum, 1% penicillin and streptomycin and maintained in 5% CO<sub>2</sub> at 37°C. C6 cells were cultured in DMEM containing 4.5 g glucose/L, 10% calf serum supplemented with iron (Hyclone), 1% penicillin and streptomycin and maintained in 10% CO<sub>2</sub> at 37°C. Details explaining construction of the G $\alpha$ s-GFP fusion protein has been described previously (Yu and Rasenick, 2002). The cDNA encoding the dominant negative K44E dynamin 1 was originally obtained from Dr. Richard Vallee (Columbia, NYC) (Herskovits et al., 1993), and it was subsequently cloned into pcDNA3.1zeo and kindly provided by Dr. Mark von Zastrow (UCSF, CA) (Chu et al., 1997). Both MCF-7 and C6 cells were seeded into delta T vision 35 mm dishes (Fisher) for live cell imaging or onto coverslips in 12 well plates for immunofluorescence. Cells were grown to 80% confluency and were transfected for 5 hours with 0.5  $\mu$ g of purified G $\alpha$ s-GFP plasmid DNA per dish or well, using a ratio of 1:5, DNA : superfect transfection reagent (Qiagen). 24 hours after G $\alpha$ s-GFP transfection, cells were used for imaging experiments. G $\alpha$ s-GFP expression in both MCF-7 and C6 cells was semi-quantified by western blotting. G $\alpha$ s-GFP expression was approximately 3 fold higher than endogenous G $\alpha$ s expression. Co-expression of G $\beta\gamma$  was not required for proper membrane association of G $\alpha$ s-GFP. Thus, presumably, G $\alpha$ s-GFP utilizes the endogenous G $\beta\gamma$  for this purpose. For the dominant negative dynamin 1 experiments, C6 cells were co-transfected for 5 hours with 0.5  $\mu$ g of G $\alpha$ s-GFP and 1.0  $\mu$ g of K44E dynamin plasmid DNA per dish, using a ratio of 1:5, DNA : superfect transfection reagent. 16 hours after the co-transfections, cells were used for imaging experiments.

**Live Cell Imaging and Immunofluorescence Microscopy.** 1 hour prior to live cell imaging, complete media was replaced with serum-free DMEM supplemented with 20 mM HEPES. Cells were maintained at 37°C during the entire period of observation using a heated microscope stage (Biotechnics, Fisher). Fluorescent images were obtained using an inverted microscope equipped for fluorescent microscopy (Nikon Eclipse TE 300, 547 nm wavelength excitation, 579 nm emission, via high pressure Nikon Xenon XBO 100 W lamp); a digital camera (RTE/CCD-1300 Y/HS, Roper Scientific; MicroMAX camera controller, Princeton Instruments Inc.; Lambda 10-2 shutter, Sutter Instruments Co.), and image-processing software (IPLab, Scanalytics Inc.). All images shown were obtained using oil immersion with a 60x objective. Scale bars shown are 10 micrometers in length. Cells were treated with 10 $\mu$ M isoproterenol (Sigma) and G $\alpha$ s-GFP trafficking was imaged in real time during receptor stimulation. For live cell imaging using transferrin Texas red ligand or fluorescent cholera toxin B-Alexa 555 (Molecular Probes), MCF-7 cells expressing G $\alpha$ s-GFP were pre-incubated with the probes for 20 minutes on ice (10  $\mu$ g/ml transferrin, 400ng/ml cholera toxin B). Cells were then washed and immediately warmed to 37°C in the presence of 10 $\mu$ M isoproterenol during imaging. For imaging studies utilizing the cholesterol chelating agent methyl- $\beta$ -cyclodextrin (CD) (Sigma), C6 cells expressing G $\alpha$ s-GFP were pre-incubated with 10mM cyclodextrin for 30 min. at 37°C, cells were washed, and subsequently imaged during treatment with 10 $\mu$ M isoproterenol. To reverse the effects of CD, cholesterol was added back to cells that were initially incubated with CD. These cells were treated for 30 min. with CD, washed with DMEM, and then treated with CD-cholesterol complexes for 90 minutes (10  $\mu$ g/ml cholesterol-CD in a molar ratio of 1:6, Sigma cat# C4951) to deliver cholesterol back to the cells (Ostrom et al., 2004). These recovered cells were washed, and subsequently imaged during treatment with

**MOL MANUSCRIPT # 8342**

10 $\mu$ M isoproterenol. For immunofluorescence microscopy, G $\alpha$ s-GFP transfected MCF-7 cells were treated with 10 $\mu$ M isoproterenol and were then fixed with 3.3% paraformaldehyde. Cells were permeabilized and blocked for 1h with 0.5% saponin, 5% BSA, 1x PBS. Cells were incubated with the following primary antibodies for 3 hours: rabbit polyclonal anti EEA1 antibody (1 $\mu$ g/ml dilution, BD Biosciences), mouse monoclonal anti LAMP1 (1  $\mu$ g/ml dilution, Univ. of Iowa Developmental Hybridoma Bank) or with rabbit polyclonal anti B<sub>2</sub>AR antibody with overnight incubation (1:100 dilution, Santa Cruz Biotech.) Cells were incubated with secondary antibodies for 1 h: goat anti mouse IgG rhodamine (1:100 dilution, Pierce) or goat anti-rabbit IgG rhodamine (1:100 dilution, Boehringer Mannheim). Coverslips were mounted and cells were imaged using fluorescence microscopy as described above. Images of live and fixed cells shown are representative of 40 to 50 cells imaged in four or more separate experiments.

**Quantification of G $\alpha$ s-GFP Internalization.** Quantification of the internalization of G $\alpha$ s-GFP was done as previously described (Yu and Rasenick, 2002). An individual blind to the experimental conditions performed all measurements. The mean of gray value within the cytoplasm in fluorescence images were collected by selecting an area that corresponded to the maximal cytoplasmic region for each cell using Scion Image from the Public Domain NIH Image Program. Mean gray values of the G $\alpha$ s-GFP fluorescence in the cytoplasm were obtained and normalized per area measured. Variation of mean gray values in cytoplasm represents the change of G $\alpha$ s-GFP fluorescence in the interior of the cell.

**Subcellular Fractionation.** Confluent C6 cells in 25 cm<sup>2</sup> flasks were treated as described in figure legends. After treatment, cells were harvested into 1 ml of PBS containing 1x protease inhibitors (Roche Diagnostics, complete protease inhibitor cocktail

**MOL MANUSCRIPT # 8342**

cat#11697498001) and homogenized with 10 strokes of a Potter-Elvehjem homogenizer, nuclei were removed by centrifugation at 1000 x g for 10 minutes, and total cellular membranes and purified cytosol were obtained by 200,000 x g centrifugation for 1 hour using a TLA-45 rotor and Beckman TL-100 table top ultracentrifuge. 10 ug samples of membrane pellet and cytosol (soluble fractions) were analyzed for G $\alpha$ s content by immunoblotting as described below.

**Isolation of Lipid Rafts/Caveolae** C6 cells were used to prepare Triton-insoluble, caveolin enriched membrane fractions by the procedure of Toki et al (Toki et al., 1999), with slight modification. C6 glioma cells were grown in 150-cm<sup>2</sup> flasks until confluent, and incubated in serum-free DMEM for 1 hour prior to all treatments. Cells were treated with 10 $\mu$ M isoproterenol for 10, 30 and 60 minutes. Some cells were treated with 10mM CD for 30 minutes to disrupt lipid rafts/caveolae, or with CD followed by treatment with CD-cholesterol complexes for 90 minutes to re-deliver cholesterol to the cells (as described above under Live Cell Imaging). Two flasks of cells for each treatment group were harvested into 1.0 ml of HEPES buffer (10mM HEPES, pH 7.5, 150mM NaCl, 1mM DTT, 0.3mM PMSF) containing 1x protease inhibitor cocktail (Roche Diagnostics). Cells were homogenized with 10 strokes of a Potter-Elvehjem homogenizer, nuclei were removed by centrifugation at 1000 x g for 10 minutes, and total cellular membranes were obtained from the supernatant by 100,000 x g ultracentrifugation. The total membrane pellet was resuspended in HEPES buffer containing 1% Triton X-100 and incubated on ice for 30 minutes. The homogenate was adjusted to 40% sucrose by addition of an equal volume of 80% sucrose prepared in HEPES buffer, and placed at the bottom of an ultracentrifuge tube. A step gradient containing 30, 15 and 5% sucrose was formed above the homogenate and centrifuged at 200,000 x g in a SW55 rotor for 18 hours. Two or three opaque bands containing the Triton X-100 insoluble floating rafts were confined between the 15 and

**MOL MANUSCRIPT # 8342**

30% sucrose layers. These bands were removed from the gradients, diluted threefold with HEPES buffer and pelleted in a microcentrifuge at 16,000 x g to obtain caveolin enriched samples of lipid rafts/caveolae. To obtain samples of the non-buoyant Triton X-100 soluble membranes, 500 $\mu$ l was removed from the bottom of each ultracentrifuge tube in the 40% sucrose layer (non-buoyant fraction). These samples were precipitated with 1mM trichloroacetic acid in HEPES buffer for 30 minutes on ice, followed by pelleting in a microcentrifuge. These samples of non-raft Triton X-100 soluble membrane protein and the Triton X-100 insoluble lipid rafts/caveolae were subsequently analyzed by immunoblotting.

**Immunoblotting.** 5 $\mu$ g of each Triton X-100 soluble membrane fraction and lipid raft/caveolae fraction was subjected to SDS-PAGE. 10 $\mu$ g of each membrane pellet and cytosol sample was also separated by SDS-PAGE. After electrophoresis, proteins were transferred to polyvinylidene difluoride (PVDF) membranes which were analyzed by western blotting. The PVDF membrane was blocked for 1 h with a Tris-buffered-saline/Tween 20 solution (10mM Tris-HCl, 159mM NaCl, and 0.1% Tween 20, pH 7.4) containing 5% dehydrated milk proteins. After 3 washes with Tris-buffered saline/Tween 20, membranes were incubated with polyclonal rabbit G $\alpha$ s antibody (1:10,000 dilution, 3 h, Dupont/NEN) or polyclonal B<sub>2</sub>AR antibody with overnight incubation (1:200 dilution, Santa Cruz Biotech.). Detection of bound antibody on the blot was assessed with a horseradish peroxidase (HRP)-conjugated, goat anti-rabbit IgG antibody (Jackson Laboratories) visualized by enhanced chemiluminescent detection (ECL, Amersham), and quantitated, after scanning densitometry using Imagequant software (Molecular Dynamics). Both the long (52kDa) and short (45kDa) forms of G $\alpha$ s were quantified together. Immunodetected G $\alpha$ s,  $\beta$ <sub>2</sub>AR and caveolin-1 bands were quantified and the integrated optical density (IOD) of each band was determined and is expressed as percent control. For some

**MOL MANUSCRIPT # 8342**

experiments, the original membranes were stripped with an acidic glycine buffer (100mM glycine, pH 2.4) and reprobbed using a monoclonal mouse anti caveolin-1 antibody (1:1000 dilution overnight, Transduction Labs) followed by immunodetection. To adjust for protein loading errors, amounts of G $\alpha$ s (both long and short isoforms) in the Triton X-100 insoluble lipid rafts/caveolae were normalized for the level of caveolin-1, and are expressed as G $\alpha$ s in the caveolin rich fraction.

**Statistical Analysis.** All quantitated data was analyzed for statistical significance using a one way ANOVA followed by Student-Newman-Keuls multiple comparison test using Prism 3.0, software package for statistical data analysis (Graph Pad Software Inc.). Differences were considered significant at  $p < 0.05$ .

## **RESULTS**

### **Real-Time Imaging of *G $\alpha$ s*-GFP during $\beta$ -Adrenergic Receptor Stimulation.**

C6 rat glioma and MCF-7 human breast adenocarcinoma epithelial cells are useful cell models for these studies, as both cell types can be easily transfected and they express endogenous  $\beta_2$ ARs which couple to *G $\alpha$ s* (Manier et al., 1992; Vandewalle et al., 1990). Both cell lines were transiently transfected with *G $\alpha$ s*-GFP. 24 hours after transfection, cells were exposed to the  $\beta$ AR agonist isoproterenol, and *G $\alpha$ s*-GFP trafficking was imaged in living cells during receptor stimulation. Prior to agonist treatment, *G $\alpha$ s*-GFP localized predominantly at the plasma membrane in C6 cells (Fig. 1A), but within 10 minutes after isoproterenol addition, many punctate vesicular structures appeared throughout the cytoplasm. During 10 minutes of treatment of both cell types, there was a marked decrease in *G $\alpha$ s*-GFP membrane localization (Fig 1A and 1B), and a contemporaneous appearance of *G $\alpha$ s*-GFP subjacent to the plasma membrane (see supplemental online video 1).

Video 1 of a representative MCF-7 cell shows that *G $\alpha$ s*-GFP at membrane extensions rapidly re-organizes to form vesicles containing this protein, and these vesicles traffic to the cell interior, indicating active endocytosis of *G $\alpha$ s*-GFP. It is noteworthy that agonist-induced removal of *G $\alpha$ s*-GFP from the plasma membrane occurred at some regions of the membrane, but not all. In C6 cells, cellular extensions of membrane enriched in *G $\alpha$ s*-GFP were repeatedly observed prior to agonist treatment, consistent with endogenous *G $\alpha$ s* localization in these cells (Donati et al., 2001). During receptor stimulation *G $\alpha$ s*-GFP was removed from these structures, suggesting internalization may occur in selective regions of the plasma membrane. Taken together, data show that during agonist stimulation of endogenous  $\beta_2$ ARs, activated *G $\alpha$ s*-GFP is removed from the plasma membrane, internalized by endocytosis, and localized in vesicles.

### **Dominant Negative Dynamin Inhibits Agonist Induced Internalization of G $\alpha$ s-GFP.**

The GTP binding protein dynamin 1 functions enzymatically to liberate vesicles from the plasma membrane during both clathrin mediated and raft/caveolae mediated endocytosis (Nichols, 2003). The K44E dominant negative dynamin 1 is deficient in GTPase activity rendering it non-functional for vesicle formation (Herskovits et al., 1993). To determine whether G $\alpha$ s internalization is dynamin dependent, C6 cells were co-transfected with G $\alpha$ s-GFP and K44E dominant negative dynamin 1 constructs and living cells were imaged during isoproterenol stimulation. Figure 2 reveals that G $\alpha$ s-GFP is expressed predominantly at the plasma membrane of co-transfected cells prior to  $\beta$ AR stimulation. During 25 minutes of isoproterenol exposure, G $\alpha$ s-GFP remained at the plasma membrane and did not internalize within vesicles or label puncta in the cellular interior. This suggests that agonist induced internalization of G $\alpha$ s-GFP is dynamin dependent.

### **Analysis of Internalized G $\alpha$ s-GFP Trafficking in the Common Compartments of the Endocytic Pathway.**

To determine the identity and trafficking of the vesicles containing internalized G $\alpha$ s-GFP, antibodies against proteins commonly used as markers for early endosomes and late endosomes/lysosomes were utilized. MCF-7 cells expressing G $\alpha$ s-GFP were treated for 30 minutes with isoproterenol. Cells were fixed and processed for immunocytochemistry using antibodies against the early endosome antigen 1 protein (EEA1) or the lysosome associated membrane protein (LAMP-1), to label early endosomes or late endosomes/lysosomes, respectively. As previously observed, isoproterenol treatment resulted in internalization of G $\alpha$ s-

**MOL MANUSCRIPT # 8342**

GFP. Fixed cells showed G $\alpha$ s-GFP in both vesicles and in the cytoplasm. Prior to agonist exposure, EEA-1 and LAMP-1 were localized to endocytic vesicles and showed a punctate localization within the cell interior. After isoproterenol treatments, internalized G $\alpha$ s-GFP did not colocalize with EEA1 or LAMP1 proteins in merged images (Fig 3A and 3B). In addition, a time course of agonist treatment was performed between 5 minutes and 1 hour, and none of the time points within this time course showed a measurable colocalization between G $\alpha$ s-GFP and EEA1 or LAMP-1 (data not shown). Lack of colocalization between G $\alpha$ s-GFP and EEA-1 or LAMP-1 suggests that G $\alpha$ s-GFP does not traffic through common endocytic compartments involving early or late endosomes or lysosomes.

Upon agonist binding,  $\beta_2$ ARs are rapidly internalized by endocytosis into clathrin coated pits and they traffic into recycling endosomes (Claing et al., 2002). Transferrin receptors also undergo agonist induced endocytosis into recycling endosomes, and the transferrin receptor and its ligand are commonly used as a marker for these endosomes. To examine if G $\alpha$ s-GFP internalized into recycling endosomes, colocalization of fluorescent transferrin with G $\alpha$ s-GFP was examined in living cells during receptor stimulation. Prior to agonist exposure at 4° C, both G $\alpha$ s-GFP and transferrin texas red were localized at the plasma membrane. 15 minutes after exposure to isoproterenol, many vesicles contained G $\alpha$ s-GFP, but these vesicles did not colocalize with internalized transferrin (Fig. 3C, merge), indicating that G $\alpha$ s-GFP does not traffic into recycling endosomes.

**Imaging of Internalized G $\alpha$ s-GFP and  $\beta_2$ AR after Receptor Stimulation.**

Since the  $\beta$ ARs that couple to and activate G $\alpha$ s are rapidly internalized after agonist binding, a primary question is whether G $\alpha$ s accompanies the receptor during endocytosis. To

## MOL MANUSCRIPT # 8342

test this,  $G_{\alpha s}$ -GFP transfected MCF-7 cells were treated with isoproterenol over a time course and cells were then fixed and incubated with antibody for the  $\beta_2$ AR. It is noteworthy that MCF-7 cells express the  $B_2$ AR subtype, which mediate isoproterenol activation of  $G_{\alpha s}$  (Draoui et al., 1991; Vandewalle et al., 1990). Isoproterenol treatment resulted in internalization of both  $G_{\alpha s}$ -GFP and  $\beta_2$ AR and numerous vesicles contained these proteins (Fig 3D).  $G_{\alpha s}$ -GFP was also found in the cytoplasm in the paraformaldehyde fixed cells, similar to the previous results (Fig 3A, 3B). Agonist evoked a slight overlap of  $G_{\alpha s}$ -GFP and  $\beta_2$ AR in internalized vesicles, but no obvious colocalization was observed (Fig. 3D, merge). Cells treated with agonist over a time course from 5 minutes to 45 minutes were similarly examined for  $G_{\alpha s}$ -GFP and  $\beta_2$ AR colocalization, but no clear colocalization could be found at any of these time points (data not shown). This lack of colocalization of  $G_{\alpha s}$ -GFP and  $\beta_2$ AR suggests that receptor and  $G_{\alpha s}$  are internalized by distinct pathways.

### **Isoproterenol Promotes $G_{\alpha s}$ -GFP and Cholera Toxin B Colocalization in Vesicles.**

Since  $G_{\alpha s}$ -GFP was not found in common endocytic compartments such as early endosomes, recycling endosomes and late endosomes, it was hypothesized that non-clathrin mediated endocytosis may be involved in  $G_{\alpha s}$ -GFP internalization. To test the idea that lipid raft/caveolae mediated endocytosis was involved, the lipid raft marker cholera toxin B was utilized to label lipid rafts in living cells. Fluorescent cholera toxin B is a common marker used to investigate the trafficking of proteins during raft mediated endocytosis in living cells (Nichols et al., 2001; van Deurs et al., 2003). It is noteworthy that it is the A subunit of cholera toxin which binds to and ADP-ribosylates  $G_{\alpha s}$  while the B subunit acts as a ligand and binds to the lipid raft localized ganglioside GM-1. Cholera toxin B is constitutively incorporated into cells

## MOL MANUSCRIPT # 8342

through lipid raft/caveolae mediated endocytosis (Orlandi and Fishman, 1998).  $G_{\alpha s}$ -GFP transfected MCF-7 cells pre-labeled with fluorescent cholera toxin B, were subsequently treated with agonist, and living cells were visualized using digital fluorescence microscopy. Prior to agonist exposure,  $G_{\alpha s}$ -GFP strongly co-localized with cholera toxin B at the plasma membrane, presumably in lipid raft microdomains (Fig 4, upper panel, merge). Fifteen minutes of agonist exposure resulted in internalization of  $G_{\alpha s}$ -GFP and uptake of cholera toxin B (Fig. 4, lower panel). Isoproterenol treatment resulted in a strong colocalization between  $G_{\alpha s}$ -GFP and cholera toxin B within internalized vesicles. Numerous vesicles contained both cholera toxin B and internalized  $G_{\alpha s}$ -GFP (arrows). This suggests that agonist activated  $G_{\alpha s}$ -GFP is internalized from lipid raft domains of the plasma membrane, possibly by caveolae or raft mediated endocytosis.

### **Isoproterenol Stimulation Increases $G_{\alpha s}$ present in the Cytosol**

Numerous studies examining the fate of  $G_{\alpha s}$  upon receptor activation have indicated that  $G_{\alpha s}$  is released into the cytosol (Ransnas et al., 1989; Thiyagarajan et al., 2002; Wedegaertner et al., 1996; Yu and Rasenick, 2002). The previous investigation utilizing  $G_{\alpha s}$ -GFP demonstrated that isoproterenol treatment results in a dissociation of the fluorescent protein from plasma membrane and the activated construct increases localization in the cytosol similar to wild type  $G_{\alpha s}$  (Yu and Rasenick, 2002). To further confirm this phenomenon, C6 cells were treated with  $\beta$  receptor agonist for 30 minutes and purified cytosol and membrane fractions were obtained and analyzed by immunoblotting for endogenous  $G_{\alpha s}$  content.  $G_{\alpha s}$  was found in the cytosol of both control and isoproterenol treated C6 cells (Fig. 5A). Isoproterenol treatment of C6 cells increased endogenous  $G_{\alpha s}$  present in the cytosol by nearly 3 fold versus control. The integrated

## MOL MANUSCRIPT # 8342

optical density (IOD) of G $\alpha$ s immunoblots were quantitated by scanning densitometry and data pooled from four experiments (Fig, 5A, n=4; Con Pellet=1053 $\pm$ 75; Con Cytosol=76 $\pm$ 13; ISO Pellet=1002 $\pm$ 68; ISO Cytosol=193 $\pm$ 22; \*p<0.05 vs. Con Cytosol). Increased cytosolic localization of G $\alpha$ s in C6 cells in response to receptor activation further confirms reports that G $\alpha$ s undergoes a subcellular redistribution after activation.

### **Analysis of G $\alpha$ s and B $_2$ AR Localization in Lipid Rafts/Caveolae.**

Colocalization of G $\alpha$ s-GFP with the lipid raft marker cholera toxin B (Fig. 4) suggests that lipid rafts may play an important role in agonist induced internalization of G $\alpha$ s. To assess biochemically the localization of endogenous G $\alpha$ s in these membrane domains, C6 cells were treated with +/- isoproterenol and Triton X-100 detergent resistant raft/caveolae membranes and Triton X-100 soluble non-raft membranes were isolated by sucrose density gradient ultracentrifugation as described in Materials and Methods. The amount of endogenous G $\alpha$ s in these membranes was determined by immunoblotting. Immunoblots were probed for both G $\alpha$ s (Fig. 5B upper panel) and the protein caveolin-1 (Fig. 5B lower panel), which is a positive marker found exclusively in lipid rafts/caveolae. G $\alpha$ s was found in both detergent resistant raft/caveolae fractions and also Triton X-100 soluble membrane fractions. Thirty minutes of isoproterenol treatment resulted in a significant increase in G $\alpha$ s protein present in the lipid raft/caveolae fractions, and a concomitant decrease in the Triton X-100 soluble membrane (non-raft) fractions (Fig. 5B). A time course of isoproterenol treatment was also performed and percent change in G $\alpha$ s protein in the lipid raft/caveolae fractions was determined (Fig. 5C). Isoproterenol treatment resulted in increased G $\alpha$ s localization in rafts by approximately 30% above control levels within 10 minutes (Fig 5C). This agonist induced increase of G $\alpha$ s in

## MOL MANUSCRIPT # 8342

rafts/caveolae indicates that  $G_{\alpha s}$  moves into these membrane microdomains subsequent to agonist activation.

Similarly, the raft and non-raft membrane localization of the  $\beta_2$ AR was determined before and after agonist stimulation. The polyclonal  $\beta_2$ AR antibody recognized two bands between the 47 and 76 kDa markers, the lowest band was estimated to be approximately 62kDa.  $\beta_2$ AR immunoreactivity appeared enriched in the Triton X-100 soluble membranes, with a lesser portion detected in the caveolin enriched raft/caveolae fractions (Fig 5D). However, after 30 minutes of isoproterenol treatment,  $\beta_2$ ARs were significantly decreased in the raft/caveolae fractions by nearly 80 percent (Fig 5D). This decrease in  $\beta_2$ AR localization in rafts/caveolae is consistent with previous reports in other cell types demonstrating that activated  $\beta_2$ ARs leave these microdomains (Ostrom et al., 2001; Rybin et al., 2000). Collectively, these data demonstrate that agonist stimulation results in subtle shifting of  $G_{\alpha s}$  and  $\beta_2$ AR in or out of raft/caveolae membranes during signaling,

### **Depletion of Membrane Cholesterol Prevents $G_{\alpha s}$ -GFP Internalization.**

Increased localization of  $G_{\alpha s}$  in lipid raft/caveolae fractions after isoproterenol exposure suggests these microdomains are important for  $G_{\alpha s}$  trafficking. Depletion of cholesterol from cell membranes using the chelating agent methyl- $\beta$ -cyclodextrin (CD) is commonly used to inhibit raft/caveolae mediated endocytosis (Nichols, 2003). Exposure of C6 cells to 10mM CD for 30 min. resulted in a profound decrease in the amount of endogenous  $G_{\alpha s}$  located in lipid rafts/caveolae, and increased the amount of  $G_{\alpha s}$  present in the soluble non-raft membranes (Fig 6A, top panel). Depletion of cholesterol with CD decreased both long and short forms of  $G_{\alpha s}$  present in raft/caveolae fractions, while the amount of caveolin-1 was not affected (Fig 6A,

**MOL MANUSCRIPT # 8342**

lower panel). These results show that removing cholesterol from cell membranes results in a significant depletion of G $\alpha$ s present in lipid rafts/caveolae. To ensure that CD was not toxic, cholesterol complexes were added back to CD treated cells as described in Materials and Methods. Adding cholesterol back to cells partially restored G $\alpha$ s localization to the raft/caveolae fractions (Fig. 6B).

To investigate if CD can block G $\alpha$ s-GFP internalization, C6 cells expressing G $\alpha$ s-GFP were exposed to 10mM CD for 30 min., followed by isoproterenol stimulation during live cell imaging. A representative C6 cell shown in Fig. 6C demonstrates that agonist induced internalization of G $\alpha$ s-GFP is prevented by cyclodextrin treatments. G $\alpha$ s-GFP remained localized on the plasma membrane during agonist stimulation, and G $\alpha$ s-GFP was not found in vesicles or punctate structures. Although CD treatment prevented G $\alpha$ s-GFP internalization, it did not inhibit clathrin mediated endocytosis of transferrin (Fig 6C, top panel 3). In similar experiments, C6 cells expressing G $\alpha$ s-GFP were initially treated with CD, and then cholesterol was delivered back to cells in the form of CD-cholesterol complexes. Images of a representative C6 cell demonstrate that CD effects are reversed when cells are provided cholesterol complexes to restore lipid rafts/caveolae (Fig 6C lower panel). Fluorescent images of C6 cells pooled from 10 independent experiments were quantitated for G $\alpha$ s-GFP internalization after treatments. These data demonstrate that disrupting rafts with cyclodextrin prevents agonist induced internalization of G $\alpha$ s-GFP, and this inhibition is reversible if cholesterol is delivered back to C6 cells. The blockade of G $\alpha$ s-GFP internalization by inhibition of raft/caveolae endocytosis suggests that G $\alpha$ s endocytosis is carried out through lipid rafts/caveolae.

### **Quantification of *G $\alpha$ s*-GFP Internalization in MCF-7 cells.**

To quantitatively assess *G $\alpha$ s* internalization in MCF-7 cells, *G $\alpha$ s*-GFP expressing cells were treated with isoproterenol for 30 minutes, fluorescent images were obtained and the grey value intensity of *G $\alpha$ s*-GFP present in the cytoplasm of cells was measured using NIH image as described in Materials and Methods. It is worth noting that this method of quantitating internalization detects the intracellular signal of *G $\alpha$ s*-GFP, regardless of whether the fluorescence is cytoplasmic or vesicular in nature. Isoproterenol treatment significantly increased *G $\alpha$ s*-GFP internalization versus control cells (Fig. 7). In contrast, cells co-transfected with *G $\alpha$ s*-GFP and dominant negative K44E dynamin 1 did not show a significant internalization in response to agonist. Similarly, cells pre-treated with the lipid raft inhibitor methyl- $\beta$ -cyclodextrin also did not show agonist mediated internalization of *G $\alpha$ s*-GFP. Quantitative data are from images of MCF-7 cells pooled from 10 independent experiments. This quantitative assessment suggests that both *G $\alpha$ s*-GFP internalization in vesicles and redistribution of *G $\alpha$ s*-GFP into the cytoplasm require intact lipid rafts/caveolae and dynamin dependent endocytosis.

## DISCUSSION

To assess the real-time trafficking of *G $\alpha$ s* during signal transduction we have utilized the well established approach of visualizing a GFP fusion protein, providing a convenient method for examining G protein trafficking in real-time (Hynes et al., 2004a; Janetopoulos and Devreotes, 2002; Yu and Rasenick, 2002). We have purposefully chosen to study *G $\alpha$ s* trafficking by expressing *G $\alpha$ s*-GFP at low levels in C6 and MCF-7 cells that express only endogenous  $\beta_2$ ARs. This model enables *G $\alpha$ s*-GFP to become activated by only endogenous  $\beta$ ARs, and we consider this approach preferable to overexpressing receptors. Real-time imaging of *G $\alpha$ s*-GFP demonstrates that isoproterenol treatment results in a removal of *G $\alpha$ s*-GFP from the plasma membrane and internalization of the protein within vesicles (Fig 1A and supplemental movie). Agonist induced internalization of *G $\alpha$ s*-GFP appears to be dynamin 1 dependent, as over expression of the K44E dominant negative dynamin mutant prevented *G $\alpha$ s*-GFP internalization (Fig. 2, Fig. 7). Data also demonstrate that *G $\alpha$ s*-GFP redistributes into the cytoplasm after receptor stimulation (Fig. 3, Fig. 4), which is consistent with previous findings about both wild type *G $\alpha$ s* and *G $\alpha$ s*-GFP (Yu and Rasenick, 2002). Note that both endogenous *G $\alpha$ s* and *G $\alpha$ s*-GFP have an identical cellular distribution, and previously both indentially redistributed in response to isoproterenol (Yu and Rasenick, 2002). In addition, agonist significantly increased the content of endogenous *G $\alpha$ s* in the cytosol of C6 cells (Fig. 5A), and this supports the many studies demonstrating a cytosolic redistribution of activated *G $\alpha$ s*.

Unexpectedly, markers for early and recycling endosomes, as well as late endosomes/lysosomes did not colocalize with internalized vesicles containing *G $\alpha$ s*-GFP (Fig. 3A, 3B, 3C). Since neither EEA-1 nor transferrin colocalized with *G $\alpha$ s*-GFP, it is unlikely that early endosomes or recycling endosomes are involved in trafficking of *G $\alpha$ s* during

**MOL MANUSCRIPT # 8342**

internalization. Consistent with these results, internalized vesicles containing G $\alpha$ s-GFP did not colocalize with endocytosed  $\beta_2$ ARs (Figm 3D), which are known to traffic into early and recycling endosomes (Claing et al., 2002). Lack of colocalization of internalized G $\alpha$ s-GFP with  $\beta_2$ ARs agrees with previous results showing that internalized G $\alpha$ s does not colocalize with the receptors in endosomes (Hynes et al., 2004b; Wedegaertner et al., 1996). These results collectively suggest that internalized G $\alpha$ s does not traffic in common compartments of the endocytic pathway.

Both lipid rafts and caveolae are cholesterol and glycolipid rich microdomains of the plasma membrane involved in a mode of endocytosis distinct from classical clathrin mediated endocytosis. Since internalized G $\alpha$ s-GFP did not colocalize with markers for common endocytic compartments, we investigated the potential involvement of lipid rafts. Using the fluorescent marker cholera toxin B, which binds to and is internalized from rafts, microscopy demonstrates that internalized G $\alpha$ s-GFP strongly colocalizes with cholera toxin B in vesicles in living cells (Fig. 4), suggesting that G $\alpha$ s is internalized from raft microdomains. It is worth noting cholera toxin B may also label compartments such as early endosomes in some cell types (Torgersen et al., 2001), but cholera toxin B is endocytosed predominantly by non-clathrin mediated endocytosis (Nichols et al., 2001; Orlandi and Fishman, 1998; van Deurs et al., 2003). Colocalization of cholera toxin B with G $\alpha$ s-GFP in internalized vesicles strongly suggests lipid rafts are involved in G $\alpha$ s internalization.

To further support this observation, biochemical studies revealed that isoproterenol treatment of C6 cells significantly increased the level of endogenous G $\alpha$ s located in Triton X-100 detergent resistant raft/caveolae fractions (Fig. 5B, 5C). The finding that in unstimulated cells, G $\alpha$ s is present in rafts/caveolae is consistent with previous studies (Oh and Schnitzer,

**MOL MANUSCRIPT # 8342**

2001; Toki et al., 1999). Increased localization of  $G_{\alpha s}$  in raft/caveolae fractions suggests  $G_{\alpha s}$  moves into these membrane domains during receptor stimulation where it may subsequently become internalized. In contrast to this, it appears that activated  $\beta_2$ ARs leave the lipid raft/caveolae microdomains (Fig. 5D), data that are consistent with reports shown in the cardiomyocyte (Ostrom et al., 2001; Rybin et al., 2000). There appears to be cellular heterogeneity concerning  $\beta_2$ AR compartmentalization.  $\beta_2$ ARs appear to be evenly distributed between raft and non-raft fractions in cardiomyocytes, however in other tissues such as vascular smooth muscle or airway epithelia,  $\beta_2$ ARs are largely excluded from rafts (Ostrom and Insel, 2004). Our data show that in C6 glioma cells,  $\beta_2$ ARs are found predominantly in non-raft fractions (Fig. 5D). Although fractions examined do not account for all  $G_{\alpha s}$  and  $\beta_2$ AR,  $G_{\alpha s}$  appears enriched in the raft/caveolae domains, while  $\beta_2$ ARs are weighted to non-rafts. Considering that the ratio of  $\beta_2$ AR to  $G_{\alpha s}$  is 1:100 in C6 cell membranes which we have calculated (Manier et al., 1992; Toki et al., 1999), this would increase the ratio of receptor to  $G_{\alpha s}$  in the non-raft regions. It is unclear how these ratio differences of  $G_{\alpha s}$  to  $\beta_2$ AR in the membrane domains contribute to  $\beta$ AR signaling. The increased association of  $G_{\alpha s}$  with rafts, but removal of  $\beta_2$ ARs from rafts during signaling further supports the hypothesis that  $G_{\alpha s}$  internalizes and traffics distinctly from the  $\beta_2$ AR.

Additional evidence supporting the hypothesis that rafts mediate  $G_{\alpha s}$  internalization can be found from the studies using methyl- $\beta$ -cyclodextrin. Incubation of C6 cells with cyclodextrin resulted in a profound decrease in  $G_{\alpha s}$  located in rafts/caveolae, demonstrating the importance of cholesterol in targeting  $G_{\alpha s}$  to these microdomains (Fig. 6A, 6B). In C6 cells pre-incubated with cyclodextrin prior to isoproterenol treatment,  $G_{\alpha s}$ -GFP internalization was blocked without affecting transferrin internalization (Fig 6C). Notably, the inhibitory effects of cyclodextrin

**MOL MANUSCRIPT # 8342**

were reversed by adding cholesterol back to cells, indicating cyclodextrin treatments are not toxic to the cells. It is noteworthy that in certain conditions, cyclodextrin has also been reported to inhibit clathrin mediated endocytosis in some cell lines (Subtil et al., 1999). However, as cyclodextrin did not prevent endocytosis of transferrin, it is unlikely that clathrin mediated endocytosis was inhibited by cyclodextrin in these experiments. Similar to C6 cells, cyclodextrin also prevented  $G_{\alpha s}$ -GFP internalization in MCF-7 cells treated with isoproterenol (Fig. 7). These results support the conclusion that  $\beta$ AR stimulation promotes  $G_{\alpha s}$  movement into lipid rafts, and that these microdomains are necessary for  $G_{\alpha s}$  internalization.

A summary of experimental results and a working model for  $G_{\alpha s}$  internalization is illustrated and described in Figure 8. This model proposes that  $G_{\alpha s}$  becomes internalized within vesicles derived from lipid rafts and that  $G_{\alpha s}$  trafficking is distinct from the  $\beta_2$ AR.

The agonist mediated internalization and trafficking of  $\beta$ ARs is a well described phenomenon, however relatively little is understood about the mechanisms regulating heterotrimeric G protein internalization. We have focused on the trafficking of  $G_{\alpha s}$  in this study, but very recent work demonstrates that  $G\beta\gamma$  is also internalized in response to  $\beta$  agonist in HEK293 cells (Hynes et al., 2004b). Internalization of activated G proteins adds a substantial complexity to the regulated signaling of  $\beta$  adrenergic receptors, one that requires proper trafficking of both receptors and their cognate G proteins to maintain signaling fidelity. Recent experiments have shown PKA phosphorylated  $\beta_1$ ARs will preferentially internalize through caveolae/rafts (Rapacciuolo et al., 2003). While cells studied in this investigation express the  $\beta_2$ AR subtype, in future experiments it will be instructive to investigate if  $\beta_1$ ARs traffic together with internalized  $G_{\alpha s}$  from rafts/caveolae.

**MOL MANUSCRIPT # 8342**

Lipid rafts/caveolae are typically thought of as membrane microdomains which spatially organize molecules to facilitate GPCR mediated signaling. However, this assumption likely depends on which G protein and receptor pathway are involved. Recently, Roth and co-workers demonstrated in C6 cells that 5HT<sub>2A</sub>/G<sub>q</sub> coupled receptor pathways are dependent on caveolae and interactions with caveolin-1, suggesting caveolae promote 5HT<sub>2A</sub>/G<sub>q</sub> signaling (Bhatnagar et al., 2004). In contrast to this, results in this report suggest G<sub>αs</sub> in lipid rafts/caveolae may be removed from membrane signaling cascades. Treatment of C6 cells with antidepressant drugs results in a removal of G<sub>αs</sub> from rafts/caveolae and an increase in cAMP synthesis, supporting the concept that shifting G<sub>αs</sub> out of raft domains enhances cAMP signaling (Donati et al., 2001; Toki et al., 1999). Two previous studies in which lipid rafts/caveolae were disrupted by cyclodextrin revealed that depletion of rafts significantly increased isoproterenol stimulated cAMP production (Miura et al., 2001; Rybin et al., 2000). Increased cAMP production in cells depleted of rafts/caveolae is consistent with the notion that these domains are effective in silencing cAMP production. Thus, isoproterenol induced movement of G<sub>αs</sub> into lipid rafts and its subsequent internalization may be involved in modulating cAMP production, however this has yet to be confirmed.

Internalization could also enable activated G<sub>αs</sub> to interact with effectors at multiple intracellular sites. Several studies have indicated G<sub>αs</sub> regulates endocytic trafficking. G<sub>αs</sub> appears to be involved in the regulation of apical transport in liver epithelia (Pimplikar and Simons, 1993), and antibodies against G<sub>αs</sub> prevent fusion of endosomal vesicles (Colombo et al., 1994). Recently, G<sub>αs</sub> has been implicated in regulating the trafficking and degradation of EGF receptors through interactions on endosomal vesicles (Zheng et al., 2004). Isoproterenol induced internalization of G<sub>αs</sub> from rafts is consistent with these findings, and may be an event enabling

## **MOL MANUSCRIPT # 8342**

activated G $\alpha$ s to traffic into the cellular interior to regulate endocytic pathways. Lastly, G $\alpha$ s has also been shown to associate with cytoskeletal elements and G $\alpha$ s is capable of activating the GTPase of tubulin and increasing microtubule dynamics (Roychowdhury et al., 1999; Sarma et al., 2003). Thus, internalization of G $\alpha$ s and association with the microtubule cytoskeleton could be a mechanism facilitating agonist mediated cell shape changes. In future studies, it will be informative to investigate the roles of both the actin and microtubule cytoskeletons in vesicular trafficking of G $\alpha$ s.

In summary, this report reveals that activated G $\alpha$ s-GFP translocates away from the plasma membrane by endocytosis, and that G $\alpha$ s trafficking is separate from  $\beta_2$ ARs. Activated G $\alpha$ s increases its localization in lipid rafts/caveolae during agonist treatment and internalization occurs from lipid raft microdomains of the plasma membrane that is dynamin 1 dependent. It is suggested that agonist induced internalization of G $\alpha$ s and association with vesicles may alter cAMP production, while enabling G $\alpha$ s to participate in intracellular signaling events.

## FIGURE LEGENDS

**FIG 1.  $\beta$ -adrenergic receptor stimulation promotes Gas-GFP internalization in living C6 and MCF-7 cells.** C6 and MCF-7 cell lines were transiently transfected with Gas-GFP. 24 hours after transfection, living cells were stimulated with 10 $\mu$ M isoproterenol, and real-time trafficking of Gas-GFP in response to agonist was assessed using digital fluorescence microscopy as described in Materials and Methods. Living cells were imaged in real time and individual frames are shown prior to and after agonist treatment at the indicated times. **A**, representative C6 cell was treated for 10 minutes with isoproterenol, arrows indicate regions where Gas-GFP dissociates from the plasma membrane. **B**, representative MCF-7 cell treated for 10 minutes with isoproterenol. During agonist treatment, Gas-GFP present in membrane extensions was rapidly reorganized and vesicles containing the protein appeared to form from these structures. Over the 8 minute period of stimulation, many vesicles containing the protein were found within the cytoplasm, and these vesicles trafficked retrogradely into the cell interior. Inset images are shown 2 minutes and 8 minutes after addition of isoproterenol, and arrows indicate retrograde trafficking of a single Gas-GFP containing vesicle. See **Fig. 1B supplemental video** online for the real-time video of these images. Scale bars = 10 $\mu$ m.

**FIG 2. K44E dominant negative dynamin overexpression prevents agonist induced internalization of Gas-GFP.** C6 cells were transiently co-transfected with Gas-GFP and dominant negative K44E dynamin 1 constructs. 16 hours after transfection, living cells were stimulated with 10 $\mu$ M isoproterenol and Gas-GFP trafficking was imaged in real time using digital fluorescence microscopy. Individual frames of Gas-GFP from a representative cell are shown prior to and after agonist exposure at the indicated times. Scale bar = 10 $\mu$ m.

**FIG 3. Internalized G $\alpha$ s does not traffic into common endocytic compartments or colocalize with  $\beta_2$  adrenergic receptors.** *A and B*, MCF-7 cells were transiently transfected with G $\alpha$ s-GFP, and cells were stimulated for 30 minutes with 10 $\mu$ M isoproterenol to promote internalization. Cells were then fixed and immunocytochemistry was performed using antibodies against the early endosome antigen 1 protein (EEA1) or the lysosome associated membrane protein (LAMP-1). *A*, representative MCF-7 cell showing no colocalization between internalized G $\alpha$ s-GFP (green) and early endosomes labeled with EEA-1 antibodies (red). *B*, representative MCF-7 cell reveals no colocalization between G $\alpha$ s-GFP (green) with late endosomes and lysosomes labeled with LAMP-1 antibodies (red). *C*, G $\alpha$ s-GFP expressing cells were pre-incubated with the recycling endosome marker transferrin Texas red ligand at 4° C. Cells were warmed to 37° C in the presence of 10 $\mu$ M isoproterenol, and colocalization between G $\alpha$ s-GFP (green) with transferrin (red) was assessed in living cells. Two representative MCF-7 cells after 15 minutes of isoproterenol treatment reveal no colocalization of G $\alpha$ s-GFP with transferrin. *D*, MCF-7 cells expressing G $\alpha$ s-GFP were stimulated for 30 minutes with 10 $\mu$ M isoproterenol to promote internalization. Cells were fixed and processed for immunocytochemistry using a  $\beta_2$ AR antibody. Two representative cells are shown, merged image indicates no colocalization between G $\alpha$ s-GFP (green) and the  $\beta_2$ AR (red). Scale bars for all images = 10 $\mu$ m.

**FIG 4. Internalized G $\alpha$ s-GFP co-localizes with the lipid raft marker cholera toxin B in living MCF-7 cells.** MCF-7 cells were transiently transfected with G $\alpha$ s-GFP and living cells were pre-incubated with the lipid raft marker, fluorescent cholera toxin B at 4° C as described in

**MOL MANUSCRIPT # 8342**

Materials and Methods. Cells were then warmed to 37° C in the presence of 10 $\mu$ M isoproterenol, and colocalization of G $\alpha$ s-GFP (green) with cholera toxin B subunit (red) was assessed using digital fluorescence microscopy. **Top panel**, representative cell expressing G $\alpha$ s-GFP (green) and labeled with cholera toxin B (red) at 4° C before isoproterenol stimulation. G $\alpha$ s-GFP and cholera toxin B strongly co-localize at the plasma membrane. **Lower panel**, Merged image of two representative cells reveals strong colocalization of G $\alpha$ s-GFP with cholera toxin B in internalized vesicles (arrows) after isoproterenol stimulation. Scale bars = 10 $\mu$ m.

**FIG 5. Isoproterenol treatment increases endogenous G $\alpha$ s localization in both cytosol and lipid rafts, while activated  $\beta_2$ -adrenergic receptors leave lipid rafts.** **A**, C6 glioma cells were treated with +/- 10 $\mu$ M isoproterenol for 30 minutes and membrane and cytosolic fractions were obtained as described in Materials and Methods. The quantity of endogenous G $\alpha$ s in the membrane pellet (P) and in cytosolic soluble fractions (S) was determined by western blotting. A representative blot (n=4) of G $\alpha$ s protein indicates isoproterenol increases the amount of G $\alpha$ s present in the cytosol, without changing the total amount of G $\alpha$ s. **B**, Agonist stimulation increases G $\alpha$ s localization in rafts. C6 glioma cells were treated with +/- isoproterenol for 30 minutes. Detergent insoluble lipid rafts/caveolae (Raft) as well as non-raft detergent soluble membranes (TXSol) were obtained by sucrose density gradient fractionation (see “Materials and Methods”). A representative blot of G $\alpha$ s protein is shown (upper panel), the same blot was re-probed for the lipid raft/caveolae marker protein caveolin-1 (lower panel). The figure is a quantitation of G $\alpha$ s protein obtained by scanning densitometry and is presented as percent control (n=3). **C**, Time course of isoproterenol treatment and G $\alpha$ s localization in the lipid raft/caveolae membrane fractions. C6 glioma cells were stimulated with isoproterenol for 10, 30

**MOL MANUSCRIPT # 8342**

and 60 minutes and rafts obtained as in B. A representative blot of G $\alpha$ s protein in lipid rafts after isoproterenol treatment is shown (upper panel), as well as caveolin-1 protein (lower panel). The figure shows percent change in G $\alpha$ s protein above control in the lipid raft/caveolae membrane fractions from four independent experiments. **D**,  $\beta_2$ -adrenergic receptors leave lipid rafts after agonist stimulation. C6 cells were treated, membrane fractions obtained as in B, and immunoblotting performed for the  $\beta_2$ AR. A representative blot of  $\beta_2$ AR protein in these fractions before and after isoproterenol treatment is shown (upper panel), and the same blot re-probed for caveolin-1 protein (lower panel). The figure is a quantitation of  $\beta_2$ AR protein obtained by scanning densitometry and is presented as percent control (n=3). Data are represented as the mean  $\pm$  SEM. \*, p<0.05 versus control. IOD = integrated optical density. Approximate molecular weight markers are shown in kDa.

**FIG 6. Disruption of lipid rafts prevents G $\alpha$ s-GFP internalization.** **A**, C6 cells were incubated with +/- 10mM methyl- $\beta$ -cyclodextrin (CD) for 30 minutes, or with cyclodextrin followed by CD-cholesterol complexes (CD+CHOL) for 90 minutes to restore cholesterol back to the cells. 1% Triton X-100 soluble membranes (TXSol) and insoluble rafts/caveolae (Raft) were obtained as described in Figure 5. A representative immunoblot shows endogenous G $\alpha$ s protein in these fractions (upper panel), and the lipid raft/caveolae marker caveolin-1 (lower panel). Approximate molecular weight markers are shown. **B**, Quantitation of G $\alpha$ s protein by scanning densitometry and presented as percent control (n=3). **C, upper panel**, C6 cells expressing G $\alpha$ s-GFP were treated with (CD) for 30 min., washed, and pre-incubated with transferrin Texas red ligand at 4 $^\circ$  C. Cells were warmed to 37 $^\circ$  C in the presence of 10 $\mu$ M isoproterenol (ISO), and G $\alpha$ s-GFP and transferrin trafficking were assessed in living cells using

**MOL MANUSCRIPT # 8342**

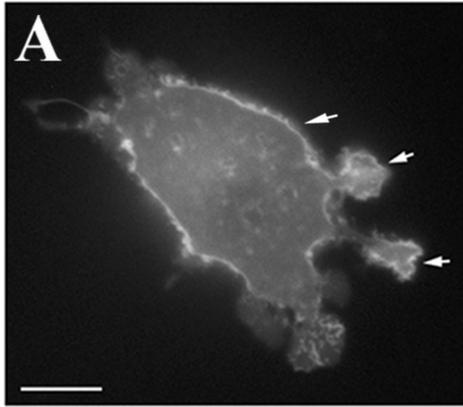

fluorescence microscopy. Images of a representative C6 cell reveals that CD treatment prevents agonist induced internalization of  $G_{\alpha s}$ -GFP, but not internalization of transferrin. **C, lower panel**, C6 cells expressing  $G_{\alpha s}$ -GFP were initially treated with CD then with CD-cholesterol complexes to restore lipid rafts. Images of a representative C6 cell reveal that CD effects can be reversed by adding cholesterol back to the cells as isoproterenol treatment of these cells restored  $G_{\alpha s}$ -GFP internalization. **D**, Quantitation of  $G_{\alpha s}$ -GFP internalization in C6 cells. The grey value intensity of  $G_{\alpha s}$ -GFP present in the cytoplasm of cells was measured using NIH image as described in Materials and Methods. Data are from images of cells pooled from 10 independent experiments (n=10). Scale bars = 10 $\mu$ m. Data are represented as the mean  $\pm$  SEM. \*, p<0.05 versus control. IOD = integrated optical density.

**FIG 7. Quantitation of  $G_{\alpha s}$ -GFP internalization.** MCF-7 expressing  $G_{\alpha s}$ -GFP were treated with +/- isoproterenol for 30 minutes and fluorescent images were obtained. The grey value intensity of  $G_{\alpha s}$ -GFP present in the cytoplasm of cells was measured using NIH image as described in Materials and Methods. Isoproterenol (ISO) treatment significantly increases  $G_{\alpha s}$ -GFP in the cytoplasm of cells, but this internalization is prevented when cells are co-transfected with dominant negative K44E Dynamin 1 (K44E Dyn), or in cells treated with the lipid raft inhibitor methyl- $\beta$ -cyclodextrin (CD). Data are from images of MCF-7 cells pooled from 10 independent experiments (n=10). \*, p<0.05 versus control.

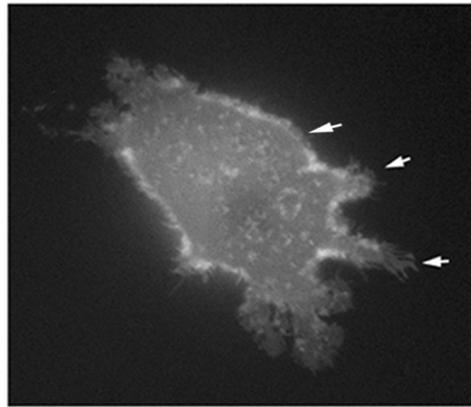

**FIG 8. A model for agonist induced internalization of  $G_{\alpha s}$ .** Upon isoproterenol binding to the  $\beta_2$ AR,  $G_{\alpha s}$  exchanges GDP for GTP resulting in dissociation of the G proteins from the receptor, and  $G_{\alpha s}$  becomes activated. Within seconds, the receptor becomes phosphorylated by G protein

**MOL MANUSCRIPT # 8342**

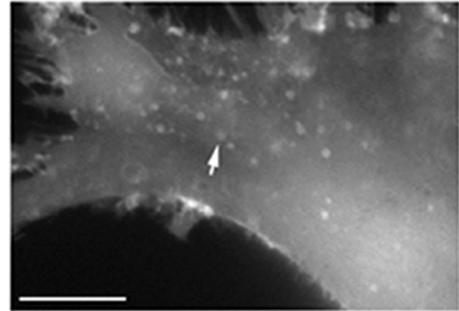

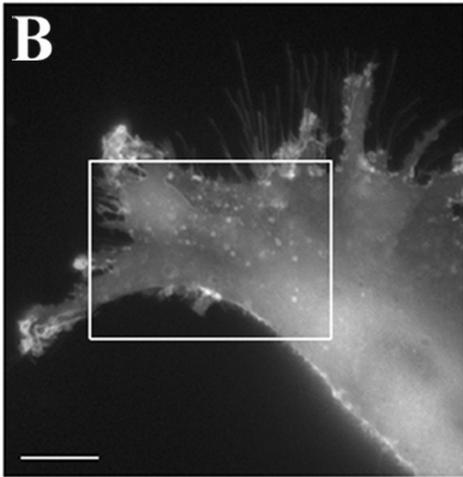

coupled receptor kinases (GRKs), and through interactions with  $\beta$ -arrestin, the receptor is recruited into clathrin coated pits and trafficked into early endosomes where ligand is removed by acidic pH (Claing et al., 2002). The receptor trafficks into classical endosomes containing EEA-1 and transferrin markers. After agonist activation, the  $\beta_2$ AR leaves lipid raft/caveolae microdomains (Fig. 5D). In contrast to this, activated  $G_{\alpha s}$  increases its association with lipid raft microdomains (Fig. 5B, 5C), and it is internalized within distinct vesicles derived from those domains. These vesicles containing  $G_{\alpha s}$  positively label with the lipid raft marker cholera toxin B (Fig. 4).  $G_{\alpha s}$  internalization from lipid rafts is dynamin 1 dependent (Fig. 2, Fig. 7) and can be inhibited by the lipid raft disrupting drug cyclodextrin (Fig. 6, Fig. 7). After receptor activation,  $G_{\alpha s}$  is also released into the cytosol (Fig. 5A), and this release may occur from either lipid rafts at the plasma membrane or from internalized vesicles. Taken together, this model suggests that activated  $G_{\alpha s}$  becomes internalized within vesicles derived from lipid rafts and that  $G_{\alpha s}$  trafficking is distinct from the  $\beta_2$ AR.
