## **Abstract**

Current operational models of agonism and allosterism quantify ligand actions at receptors where agonist concentration-response relationships are non-hyperbolic by introduction of a transducer slope that relates receptor occupancy to response. However, for some receptors, non-hyperbolic concentration-response relationships arise from multiple endogenous agonist molecules binding to a receptor in a cooperative manner. Thus, we developed operational models of agonism in systems with cooperative agonist binding, and evaluated the models by simulating data describing agonist effects. The models were validated by analyzing experimental data demonstrating the effects of agonists and allosteric modulators at receptors where agonist binding follows hyperbolic ( $M_4$  muscarinic acetylcholine receptors) or non-hyperbolic relationships (metabotropic glutamate receptor 5 and calcium-sensing receptor). For hyperbolic agonist-concentration response relationships, no difference in estimates of ligand affinity, efficacy or cooperativity were observed when the slope was assigned to either a transducer slope or to an agonist binding slope. In contrast, for receptors with non-hyperbolic agonist concentration-response relationships, estimates of ligand affinity, efficacy or cooperativity varied depending on the assignment of the slope. The extent of this variation depended upon the magnitude of the slope value, agonist efficacy, and, for allosteric modulators, on the magnitude of cooperativity. The modified operational models described herein are well suited to analyzing agonist and modulator interactions at receptors that bind multiple orthosteric agonists in a cooperative manner. Accounting for cooperative agonist binding is essential to accurately quantify agonist and drug actions.

## **Significance statement**

Some orthosteric agonists bind to multiple sites on a receptor, but current analytical methods to characterize such interactions are limited. Herein, we develop and validate operational

MOL # 118091

models of agonism and allosterism for receptors with multiple orthosteric binding sites, and demonstrate that such models are essential to accurately quantify agonist and drug actions. These findings have important implications for the discovery and development of drugs targeting receptors such as the calcium-sensing receptor, which binds at least five calcium ions.

## Introduction

The past 30 years have seen major advances in quantifying the relationship between receptor occupancy and response, with the operational model of agonism (Black and Leff, 1983) representing one of the most common analytical approaches. The operational model of agonism describes agonist effects based on agonist affinity ( $K_A$ ) and observed efficacy in a given test system. The latter is defined by a transducer ratio,  $\tau$ , which is a function of both tissue- and agonist-specific components; it is the ratio of the total receptor number ( $R_T$ ) and a transducer parameter ( $K_E$ ) that defines the avidity with which a given agonist-occupied receptor complex promotes the final observed pharmacological effect. As such, the operational model of agonism is a useful tool for quantifying agonism in a comparable manner across different test systems (Black and Leff, 1983), and has subsequently been extended or modified to also quantify effects of allosteric modulators and biased agonists (Kenakin, 2012; Leach et al., 2010; Leach et al., 2007).

The operational model of agonism has been most commonly applied to characterize the activity of agonists that display both rectangular hyperbolic or non-hyperbolic concentration-response curves, i.e., normally empirically characterized by Hill slopes that are equal to or different from unity, respectively. The key underlying assumption in the majority of instances to date where an agonist concentration-response curve displays a Hill slope significantly

MOL # 118091

different from 1 has been ascribed in the most common form of the operational model to differences in the post-receptor machinery that transduce occupancy to response, i.e., through introduction of a so-called “transducer slope” ( $n$ ) (Black et al., 1985). For instance, steep or shallow Hill slopes could arise due to changes in the sensitivity of one or more steps in a receptor’s signal transduction mechanism, while the initial agonist-receptor binding event is assumed to be characterized by a simple hyperbolic one-to-one relationship. However, for ion channels and a number of G protein-coupled receptors (GPCRs), particularly the class C GPCR subfamily, non-hyperbolic concentration-response relationships can also arise from cooperative binding of multiple equivalents of the same endogenous agonist molecule prior to any subsequent processing of the stimulus by the cellular transduction machinery. For example, while a number of small molecule calcium-sensing receptor (CaSR) agonists produce responses characterized by Hill slopes close to unity (Cook et al., 2015; Keller et al., 2018), indicating a transducer slope equal to unity, it is also well established that CaSR responses to its endogenous activator, extracellular calcium ( $\text{Ca}^{2+}_o$ ) and other divalent cations are characterized by extremely high Hill slopes, ranging from 2 to 4 (Brown, 1983; Davey et al., 2012; Leach et al., 2015). The most parsimonious explanation to account for these disparate observations is that the operational transducer slope linking CaSR agonist occupancy to response can adequately be described by a transducer slope equal to unity, which suggests that the cooperativity observed in response to activators such as ( $\text{Ca}^{2+}_o$ ) ions arises at the level of binding, not function. This is also in accord with known pharmacological and structural studies of the CaSR that have identified multiple binding sites for  $\text{Ca}^{2+}_o$  ions (Geng et al., 2016). As a consequence, the classic operational model of agonism as applied to concentration-response curves of non-unit Hill slopes is suboptimal for such situations.

MOL # 118091

Herein, we sought to develop and evaluate an operational model of agonism that describes orthosteric agonist binding to multiple sites in a cooperative manner, referred to as the “cooperative agonist operational model”. The cooperative agonist operational model was superior to the original Black and Leff operational model of agonism in fitting  $\text{Ca}^{2+}_o$ -CaSR concentration-response data. We also extended this cooperative agonist operational model to incorporate allosteric modulation of the affinity and efficacy of an agonist that binds cooperatively to multiple sites. This “operational model of allosterism with cooperative agonist binding” was fitted to data describing the actions of CaSR positive allosteric modulators (PAMs) and negative allosteric modulators (NAMs), and revealed that if cooperative agonist binding is not taken into consideration, under- or overestimates of PAM and NAM affinity and cooperativity can occur.

## Materials and methods

### *Materials*

Dulbecco’s modified Eagle’s medium (DMEM), FlpIn HEK TREx cells, blasticidin S HCl and FBS were obtained from Invitrogen (Carlsbad, USA), whilst hygromycin B was from Roche (Mannheim, Germany). Fluo-8 AM was from Abcam (Cambridge, MA, USA).

### *CaSR-expressing HEK293 cell lines*

The generation of DNA and FlpIn HEK TREx cells stably expressing c-myc-tagged WT CaSR in pcDNA5/ft/TO have been described previously (Davey et al., 2012; Leach et al., 2016). FlpIn HEK TREx CaSR cells were maintained in DMEM containing 5% FBS, 200  $\mu\text{g}/\text{mL}$  hygromycin B and 5  $\mu\text{g}/\text{mL}$  blasticidin S HCl. To generate a tetracycline-inducible FlpIn HEK cell line stably expressing an N terminally-truncated CaSR, N terminally-truncated CaSR corresponding to amino acids 600-903 with an N-terminal influenza

MOL # 118091

haemagglutinin signal peptide followed by a c-myc epitope and rhodopsin signal peptide in pcDNA3.1+ (Leach et al., 2016) was transferred to pcDNA5/ft/TO using BamHI and NotI restriction sites. FlpIn HEK TREx cells were seeded into 25 cm<sup>2</sup> flasks in DMEM containing 5% FBS and allowed to reach 80% confluency. Cells were transfected with 0.5 µg pcDNA5/ft/TO containing the N terminally-truncated CaSR plus 5 µg POG44 with lipofectamine 2000 (1:4 DNA:lipofectamine 2000) according to manufacturer's instructions. The following day, cells were transferred to a T75 cm<sup>2</sup> flask, and 24 hrs later DMEM was replaced with DMEM containing 5% FBS, 200 µg/mL hygromycin and 5 µg/mL blasticidin S HCl. Selection DMEM was replaced every 3 days until untransfected cells had died (~10 days), and antibiotic-resistant cells were expanded and maintained in DMEM containing 5% FBS, 200 µg/mL hygromycin and 5 µg/mL blasticidin S HCl. All cell lines were routinely tested for mycoplasma contamination using the Lonza™ MycoAlert™ mycoplasma detection kit.

*Determination of WT and N terminally-truncated CaSR cell surface expression using FACS*

FlpIn HEK TREx WT and N terminally-truncated CaSR expressing cells were seeded at 80,000 cells/well into a 96-well plate and expression was induced with 100 ng/mL tetracycline overnight at 37°C. The following day, cells were harvested, washed in 1 x PBS with 0.1% BSA and 2 mM EDTA (wash buffer) by centrifugation (350 x g, 4°C for 3 min) before resuspension and 30 min incubation in 100 µL blocking buffer (1 x PBS, 5% BSA and 2 mM EDTA) containing 1 µg/mL AF647-conjugated 9E10 made in house as previously described (Cook et al., 2015). Cells were washed as previously described and resuspended in wash buffer containing propidium iodide. Live cell fluorescence was measured using a FACS Canto (Becton Dickinson).

MOL # 118091

### *Calcium mobilization assays*

Cells were seeded in clear 96-well plates coated with poly-D-lysine ( $50 \mu\text{g mL}^{-1}$ ) at 80,000 cells/well and incubated overnight in the presence of 0 or  $100 \text{ ng mL}^{-1}$  tetracycline. The following day, cells were washed with assay buffer (150 mM NaCl, 2.6 mM KCl, 1.18 mM  $\text{MgCl}_2$ , 10 mM D-Glucose, 10 mM HEPES, 0.1 mM  $\text{CaCl}_2$ , 0.5 % BSA and 4 mM probenecid at pH 7.4) and loaded with Fluo-8 AM ( $1 \mu\text{M}$  in assay buffer) for 1 h at  $37^\circ\text{C}$ . Cells were washed with assay buffer prior to the addition of fresh assay buffer.

For all studies, each well was treated with a single agonist concentration. The release of  $\text{Ca}^{2+}_i$  was measured at  $37^\circ\text{C}$  using a Flexstation<sup>®</sup> 1 or 3 (Molecular Devices; Sunnyvale, California). Fluorescence was detected for 60 sec at 490 nm excitation and 520 nm emission and the peak  $\text{Ca}^{2+}_i$  mobilization response (approximately 12 sec after agonist addition) was used for the subsequent determination of the agonist response. Relative peak fluorescence units were normalized to the fluorescence stimulated by  $1 \mu\text{M}$  ionomycin to account for differences in cell number and loading efficiency.

### *Model derivation and data analysis*

The derivation of operational models describing the effect of an agonist in the absence or presence of an allosteric modulator at a receptor with multiple agonist binding sites is presented in Appendix 1. The script input to use the two equations in the program, Graphpad Prism, is also presented in the Appendix.

Data simulations were performed using the original Black and Leff operational model of agonism, referred to herein as the Black and Leff model (Eq 1), or a modified cooperative agonist operational model (Eq 2), where an additional slope ( $nB$ ) was incorporated to account

MOL # 118091

for multiple agonist binding sites and thus the steepness of the slope describing the agonist concentration–occupancy relationship.

$$\text{Effect} = \frac{E_m \tau_A^{nT} [A]^{nT}}{\tau_A^{nT} [A]^{nT} + ([A] + K_A)^{nT}}$$

Eq 1

$$\text{Effect} = \frac{E_m \tau_A^{nT} [A]^{nBnT}}{\tau_A^{nT} [A]^{nBnT} + ([A]^{nB} + K_A^{nB})^{nT}}$$

Eq 2

where  $[A]$  is the agonist concentration,  $K_A$  is the agonist equilibrium dissociation constant;  $\tau_A$  is an operational measure of agonist efficacy;  $E_m$  is the maximal system response;  $nT$  is the transducer slope linking agonist concentration to response; and  $nB$  is the binding slope linking agonist concentration to receptor occupancy.

For simplicity, the modified cooperative operational model of agonism (Eq 2) makes the following assumptions:

- i. The receptor is either empty or fully occupied, and only the fully occupied receptor exerts an effect. The lack of partially occupied receptor molecules could arise if multiple agonist molecules bind simultaneously to the receptor, or if agonist molecules bind sequentially with high positive cooperativity. Thus, once one binding site is occupied, positive cooperativity drives occupancy of all other sites. The latter scenario is most likely, hence why we have called this model the cooperative agonist operational model.
- ii. The model cannot discern cooperativity between the multiple binding sites, thus  $nB$  may not be the true number of binding sites.  $nB$  is therefore a binding slope coefficient;

MOL # 118091

- iii.  $K_A$  is a geometric mean of the microscopic dissociation constants for each binding site.

Agonist concentration response curves were fitted to Eq 1 or 2 to quantify agonist affinity and efficacy. When fitting experimental data to Eq 2, the transducer slope was constrained to unity (see Results for validation of this assumption).

Data describing the interaction between glutamate and PAMs and NAMs at mGlu<sub>5</sub>, or between ACh and LY2033298 at the M<sub>4</sub> muscarinic acetylcholine receptor (mAChR), were fitted to our original operational model of allosterism (Eq 3) or to the new operational model of allosterism with cooperative agonist binding (Eq 4). For simplicity and for the purpose of fitting experimental data, Eqs 3-8 assume a single allosteric modulator binding site, and therefore do not account for modulator cooperative binding.

$$\text{Effect} = \frac{E_m(\tau_A[A](K_B + \alpha\beta[B]) + \tau_B[B][K_A])^{nT}}{([A]K_B + K_A K_B + K_A[B] + \alpha[A][B])^{nT} + (\tau_A[A](K_B + \alpha\beta[B]) + \tau_B[B]K_A)^{nT}}$$

Eq 3

$$\text{Effect} = \frac{E_m(\tau_A[A]^{nB}(K_B + \alpha\beta[B]) + \tau_B[B][K_A]^{nB})^{nT}}{([A]^{nB}K_B + K_A^{nB}K_B + K_A^{nB}[B] + \alpha[A]^{nB}[B])^{nT} + (\tau_A[A]^{nB}(K_B + \alpha\beta[B]) + \tau_B[B]K_A^{nB})^{nT}}$$

Eq 4

where  $K_A$  is the equilibrium dissociation constant of the orthosteric agonist and was fixed in some instances to the affinity determined in radioligand binding assays (Leach et al., 2010; Mutel et al., 2000);  $K_B$  is the equilibrium dissociation constant of the allosteric ligand;  $\tau_A$  and  $\tau_B$  are the operational efficacies of the orthosteric agonist and allosteric ligand, respectively;  $\alpha$  and  $\beta$  are the allosteric effects on orthosteric agonist affinity and efficacy, respectively (it should be noted that  $\beta$  is not a reciprocal efficacy cooperativity factor (Giraldo, 2015; Leach et al., 2007));  $[A]$  and  $[B]$  are the orthosteric agonist and allosteric ligand concentrations,

MOL # 118091

respectively;  $E_m$  is the maximal system response;  $nT$  is the transducer slope linking agonist concentration to response; and  $nB$  is the slope of agonist binding linking agonist concentration to occupancy.

To fit the operational model of allosterism to data describing the interaction between  $Ca^{2+}_o$  and cinacalcet at the CaSR, the original operational model of allosterism shown by equation 3 was simplified, because for a full agonist like  $Ca^{2+}_o$  (i.e., one that generates the maximal system response at submaximal receptor occupancies),  $K_A \gg [A]$ . Further, because the CaSR's orthosteric agonist,  $Ca^{2+}_o$ , was present in the assay buffer, contaminating agonist was included in the equations used to analyze CaSR PAM (cinacalcet) and NAM (NPS2143) data (Keller et al., 2018). Therefore, data describing the interaction between  $Ca^{2+}_o$  and cinacalcet or NPS2143 at the CaSR were fitted to the original operational model of allosterism with contaminating agonist (Eqs 5 and 6, respectively) or to an operational model of allosterism with cooperative agonist binding and contaminating agonist (Eqs 7 and 8, respectively):

$$\text{Effect} = \frac{E_m ([A+C](K_B + \alpha\beta[B]) + \tau_B [B][EC_{50}])^{nT}}{[EC_{50}]^{nT} (K_B + [B])^{nT} + ([A+C](K_B + \alpha\beta[B]) + \tau_B [B][EC_{50}])^{nT}}$$

Eq 5

where  $EC_{50}$  is the agonist concentration that elicits a half maximal response (it should be noted that inclusion of  $[EC_{50}]$  involves some simplifying assumptions that facilitate data fitting (Aurelio et al., 2009; Giraldo, 2015));  $[C]$  is the contaminating agonist concentration; and all other parameters are as described for Eq 3.

$$\text{Effect} = \frac{E_m (\tau_A [A+C](K_B + \alpha\beta[B]) + \tau_B [B][K_A])^{nT}}{([A]K_B + K_A K_B + K_A [B] + \alpha[A+C][B])^{nT} + (\tau_A [A+C](K_B + \alpha\beta[B]) + \tau_B [B]K_A)^{nT}}$$

Eq 6

where  $[C]$  is the contaminating agonist concentration and all other parameters are as described for Eq 3.

MOL # 118091

$$\text{Effect} = \frac{E_m ([A+C]^{nB} (K_B + \alpha\beta[B]) + \tau_B [B] [EC_{50}]^{nB})^{nT}}{[EC_{50}]^{nBnT} (K_B + [B])^{nT} + ([A+C]^{nB} (K_B + \alpha\beta[B]) + \tau_B [B] [EC_{50}]^{nB})^{nT}}$$

Eq 7

where  $EC_{50}$ ,  $K_B$ ,  $\tau_B$ ,  $\alpha$ ,  $\beta$ ,  $[A]$ ,  $[B]$ ,  $[C]$  and  $E_m$  are as described for Eq 5 and  $nB$  is the slope of agonist binding linking agonist concentration to occupancy.

$$\text{Effect} = \frac{E_m (\tau_A [A+C]^{nB} (K_B + \alpha\beta[B]) + \tau_B [B] [K_A]^{nB})^{nT}}{([A+C]^{nB} K_B + K_A^{nB} K_B + K_A^{nB} [B] + \alpha [A+C]^{nB} [B])^{nT} + (\tau_A [A]^{nB} (K_B + \alpha\beta[B]) + \tau_B [B] K_A^{nB})^{nT}}$$

Eq 8

where  $[C]$  is the contaminating agonist concentration and all other parameters are as described for Eq 4.

Simulated data was fitted to the following Hill equation:

$$\text{Effect} = \frac{[A]^{nH} E_{\max}}{[A]^{nH} + EC_{50}^{nH}}$$

Eq 9

where  $[A]$  is agonist concentration;  $E_{\max}$  is the maximum agonist effect;  $EC_{50}$  is the agonist concentration that produces half the maximum agonist effect; and  $nH$  is the Hill slope.

Non-linear regression analysis was performed in GraphPad Prism 7 or 8. Potency, affinity, cooperativity and efficacy parameters were estimated as logarithms (Christopoulos, 1998). An extra sum of squares F test was used to determine whether data were fitted best when the Hill slope, binding slope or transducer slope ( $nH$ ,  $nB$  or  $nT$ , respectively) were significantly different from unity, where  $p < 0.05$  was considered significant.

MOL # 118091

## Results

### *The contribution of slope factors to agonist concentration-response relationships*

We first evaluated the contribution of the agonist binding slope ( $nB$ ) or transducer slope ( $nT$ ) to the concentration-response curve of two agonists with different efficacies, by simulating variations in  $nB$  or  $nT$  using the cooperative agonist operational model (Eq 2). We specifically wanted to evaluate a system with cooperative agonist binding, therefore we based our simulations on  $\text{Ca}^{2+}_o$  activation of the CaSR. The  $\text{Ca}^{2+}_o$  concentration-response relationship for the CaSR's best characterized physiological role, inhibition of parathyroid hormone (PTH) secretion, occurs over a  $\text{Ca}^{2+}_o$  concentration range of 0.8 – 1.5 mM with an  $\text{EC}_{50}$  of ~1.2 mM (Brown, 1983). Thus, for these simulations, the affinity of the agonist ( $K_A$ ) was assumed to be 1.2 mM and  $nB$  or  $nT$  were assumed to be between 1 and 3. Simulated data was subsequently fitted to a Hill equation (Eq 9). Unsurprisingly, increasing  $nB$  or  $nT$  increases the Hill slope of the agonist concentration-response curve (Figure 1, Table 1). Further, increasing  $nT$  decreases agonist potency. Interestingly, the effect of  $nB$  on agonist potency depends on the magnitude of  $nT$  and  $\tau_A$ . For instance, increasing  $nB$  decreases agonist potency for higher efficacy agonists ( $\tau_A > 3$ ). However, for lower efficacy agonists ( $\tau_A < 1$ ), increasing  $nB$  decreases agonist potency when  $nT \leq 1$ , but increases agonist potency when  $nT \geq 2$ .

We next sought to directly compare the influence of the binding or transducer slope by simulating concentration-response curves for agonists with varying efficacies using the Black and Leff operational model (Eq 1, which contains a transducer slope,  $nT$ ) and the cooperative agonist operational model (Eq 2, which contains a transducer and a binding slope,  $nT$  and  $nB$ , respectively). As can be seen in Figure 2 and Table 2, when  $nT$  or  $nB$  are equal to 1, variations in  $\tau_A$  have an identical effect on empirical agonist concentration-response

MOL # 118091

parameters (potency, Hill slope or  $E_{\max}$ ) regardless of the model. In contrast, when  $nT$  or  $nB$  are greater than 1, variations in  $\tau_A$  result in major differences in the agonist concentration-response profile predicted with the two different operational models of agonism. Specifically, the Black and Leff model predicts that high efficacy agonists have greater potency relative to affinity (due to amplification of the “steps” between agonist binding and response), while for low efficacy agonists, the  $EC_{50}$  may be less than the  $K_A$  for curves that possess non-unity Hill slopes. The latter was previously noted by Black and Leff (Black et al., 1985). Further, the Hill slope decreases alongside decreases in  $\tau_A$ . In comparison, the cooperative agonist operational model predicts that when  $nT$  is 1, agonist  $EC_{50}$  may approach but not be less than its  $K_A$ , regardless of whether  $nB$  is greater than 1, and there is no effect of  $\tau_A$  on the Hill slope of the agonist concentration-response curve (Figure 2, Table 2).

#### *Quantification of experimentally derived agonist concentration-response data*

We next tested whether our simulations were recapitulated in a functional assay that measures CaSR activation. To do so, we measured  $Ca^{2+}_o$ -mediated  $Ca^{2+}_i$  mobilization following titration of CaSR expression using a tetracycline inducible system. In the absence of tetracycline, the maximal response to  $Ca^{2+}_o$  is approximately 50% of the maximal response obtained under full induction of receptor expression (100 ng/mL tetracycline). In this system, fitting a Hill equation (Eq 9) to both data sets indicated that the data were fitted best when the Hill slope was unchanged with different receptor expression levels (i.e. different magnitudes of  $\tau_A$ ) ( $p < 0.05$ , extra sum-of-squares F test; data not shown). For the CaSR, the small molecule allosteric agonists, AC265347 or calcimimetic B, activate the CaSR with a Hill slope of 1 (Cook et al., 2015; Keller et al., 2018). Similarly, when cooperative agonist binding is prevented by removal of the CaSR’s N terminal domain and consequently the primary  $Ca^{2+}_o$  binding sites, the Hill slope for  $Ca^{2+}_o$  is not significantly different to unity (see

MOL # 118091

below). This provides experimental evidence that the CaSR's transducer slope is equal to unity, and that the steep Hill slopes observed for  $\text{Ca}^{2+}_o$  at the full-length CaSR thus likely arise from a binding slope greater than 1. Thus, when fitting CaSR experimental data to the cooperative agonist operational model,  $nT$  was constrained to unity.

When the data were fitted to the classic Black and Leff model, the estimated  $K_A$  was 0.2 mM (Figure 3A, Table 3). In comparison, the cooperative agonist operational model yielded a  $K_A$  estimate of 1.1mM, which is in close agreement with the  $EC_{50}$  (1.2 mM) of  $\text{Ca}^{2+}_o$  for suppressing PTH release (Brown, 1983) and  $\text{Ca}^{2+}_o$  affinity estimates for the CaSR extracellular domain determined using spectroscopic approaches (Huang et al., 2009; Zhang et al., 2014). For both analyses, data were fitted best when the binding slope (cooperative agonist operational model) or transducer slope (Black and Leff model) were different to unity ( $p < 0.05$ , extra sum of squares F test).

To further validate our simulations in a functional assay, we next sought to quantify the affinity and efficacy of a CaSR partial agonist. To do so, we took advantage of observations that in comparison to at the WT CaSR (Figure 3B),  $\text{Ca}^{2+}_o$  acting via the 7 transmembrane (7TM) domain is a partial agonist at an N-terminally truncated CaSR (depicted in Figure 3C) relative to the trivalent cation, gadolinium ( $\text{Gd}^{3+}_o$ ) (Figure 3D). FACs analysis confirmed cell surface expression of the WT and N terminally-truncated CaSR (Supplemental Figure 1). We quantified  $\text{Ca}^{2+}_o$  affinity and efficacy at the N terminally-truncated CaSR using the original Black and Leff model or the cooperative agonist operational model (Table 3). In both instances, data were best fitted when the binding slope (cooperative agonist operational model) or transducer slope (Black and Leff model) were not different to unity ( $p < 0.05$ , extra sum of squares F test), consistent with a reduction in positively cooperative  $\text{Ca}^{2+}_o$  binding, as

MOL # 118091

would be expected upon removal of the four primary  $\text{Ca}^{2+}_o$  binding sites located in the N terminal domain (Geng et al., 2016). Thus, parameters determined at the N terminally-truncated receptor were identical regardless of the equation used to analyze the data.  $\text{Ca}^{2+}_o$  affinity and cooperativity estimates at the N terminally-truncated receptor were compared to those determined at the full-length WT CaSR, indicating a reduction in  $\text{Ca}^{2+}_o$  affinity at the N terminally-truncated receptor in comparison to WT (Table 3), again consistent with removal of the primary  $\text{Ca}^{2+}_o$  binding sites. However, due to a lower estimate of  $\text{Ca}^{2+}_o$  efficacy at the WT receptor when WT data were analyzed using the Black and Leff model, only the cooperative agonist operational model accurately quantified a reduction in  $\text{Ca}^{2+}_o$  efficacy at the N terminally-truncated receptor in comparison to at the WT receptor. This is consistent with a lower  $\text{Ca}^{2+}_o$   $E_{\text{max}}$  at the N terminally-truncated receptor (~60% of the maximum response stimulated by  $\text{Gd}^{3+}_o$ ) in comparison to WT (~100%  $\text{Gd}^{3+}_o$   $E_{\text{max}}$ ) (Table 3). Thus, only the cooperative agonist operational model accurately estimated  $\text{Ca}^{2+}_o$  partial agonism at the N terminally-truncated receptor.

### *Quantifying allosteric interactions in systems with different degrees of cooperative agonist binding*

Having established that the cooperative agonist operational model best fitted our  $\text{Ca}^{2+}_o$ -WT CaSR concentration-response curves with Hill slopes greater than 1, we next extended this model to allow for quantification of allosteric modulation of an agonist response. The operational model of agonism and allosterism (Leach et al., 2010; Leach et al., 2007) (referred to herein as the original operational model of agonism and allosterism) combines the allosteric ternary complex models developed by Stockton et al. and Ehlert (Ehlert, 1988; Stockton et al., 1983) and the Black and Leff operational model of agonism, to account for allosteric effects on agonist affinity and efficacy. In our original model (Leach et al., 2007),

MOL # 118091

the allosteric modulator can also possess intrinsic efficacy. Introduction of a slope in that model once again assumed that the slope linked occupancy to response, not to the original binding events, which were assumed to be described as simple one-to-one hyperbolic functions. Therefore, we adapted this operational model of allosterism to account for cooperative agonist binding, referred to hereafter as the “operational model of allosterism with cooperative agonist binding”. In order to validate this operational model of allosterism with cooperative agonist binding, we reanalyzed existing data demonstrating positive and negative allosteric modulation at three model GPCRs with different agonist Hill slopes: CaSR (a class C GPCR where the primary endogenous agonist,  $\text{Ca}^{2+}_o$ , has a Hill slope of 2 – 4), mGlu<sub>5</sub> (a class C GPCR where the primary endogenous agonist, L-glutamate, has a Hill slope of ~1.8) (Sengmany and Gregory, 2016), and M<sub>4</sub> mAChR (a class A GPCR where the endogenous agonist, acetylcholine, has a Hill slope of 1) (Leach et al., 2011; Leach et al., 2010) (Supplemental Figure 2). In all instances,  $nT$  was assumed to be unity and all allosteric modulators were assumed to bind to a single site (i.e. the modulator binding slope is unity).

For the CaSR, we analyzed allosteric modulation of  $\text{Ca}^{2+}_o$  by cinacalcet (PAM) or NPS2143 (NAM) (Leach et al., 2016) with the original operational model of agonism and allosterism with contaminating (i.e., ambient buffer) agonist (Eq 5 or 6, respectively) and the newly derived operational model of allosterism with cooperative agonist binding and contaminating agonist (Eq 7 or 8, respectively) (Figure 4). Similar to our analysis of agonist concentration-response curves, data were fitted best when the binding slope (operational model of allosterism with cooperative agonist binding) or transducer slope (original operational model of agonism and allosterism) were different to unity ( $p < 0.05$ , extra sum of squares F test). Compared to the original operational model of agonism and allosterism, the estimated affinity for  $\text{Ca}^{2+}_o$  determined using the operational model of allosterism with cooperative agonist

MOL # 118091

binding (1.4 mM; Table 4) was once again closer to the assumed  $\text{Ca}^{2+}_o$  affinity based on its  $\text{EC}_{50}$  for suppression of PTH release (1.2 mM) and quantification of the  $\text{Ca}^{2+}_o$   $K_A$  at the extracellular domain using spectroscopic approaches (3-5 mM) (Huang et al., 2009; Zhang et al., 2014). Further, the estimated affinity and negative cooperativity of NPS2143 were greater (5.5- and 35-fold, respectively) when cooperative agonist binding was factored into the analysis (Table 4). For the PAM, cinacalcet, the operational model of allosterism with cooperative agonist binding yielded a 3-fold lower affinity estimate but an 8-fold greater magnitude of positive cooperativity.

We next analyzed allosteric modulation of glutamate at  $\text{mGlu}_5$  (Eq 3 or 4) by a representative “full” NAM (MPEP) that completely inhibits glutamate-mediated activation of  $\text{Ca}^{2+}_i$  mobilization, a “partial” NAM (M-5MPEP) that only partially inhibits glutamate-mediated activation of  $\text{Ca}^{2+}_i$  mobilization (Sengmany et al., 2019), a pure PAM (VU-29) and a mixed PAM-agonist (DPFE) (Sengmany et al., 2017). Similar to analyses at the  $\text{CaSR}$ , all data were fitted best when the binding slope (operational model of allosterism with cooperative agonist binding) or transducer slope (original operational model of agonism and allosterism) were different to unity ( $p < 0.05$ , extra sum of squares F test). However, for each modulator, the affinity and cooperativity estimates were similar (within 3-fold) irrespective of the analytical model applied (Figure 5, Table 5). Therefore, although the glutamate- $\text{mGlu}_5$  concentration-response relationship has a Hill slope greater than unity, quantification of allosteric interactions at  $\text{mGlu}_5$  is largely unaffected by whether the empirical slope is assumed to be determined by the transducer slope or the agonist binding slope.

For the  $\text{M}_4$  mAChR, we analyzed previously published positive allosteric modulation of ACh by the PAM-agonist, LY2033298, in [ $^{35}\text{S}$ ]GTP $\gamma$ S binding assays (Leach et al., 2010) (Eq 3 or

MOL # 118091

4). As expected, in the absence of cooperative ACh binding at the M<sub>4</sub> mAChR, data for the interaction between ACh and LY2033298 were fitted best by both operational models of agonism and allosterism when the slope was not different to unity ( $p < 0.05$ , extra sum of squares F test), and both equations therefore yielded identical estimates of affinity and cooperativity (Figure 6, Table 6).

We next sought to establish why quantification of PAM and NAM affinity and cooperativity were not greatly affected by the assignment of the slope at mGlu<sub>5</sub>, where the glutamate Hill slope is greater than unity. To do so, we simulated the interaction between an orthosteric agonist and a NAM or PAM with the operational model of allosterism with cooperative agonist binding and analyzed the simulated data with the original operational model of agonism and allosterism. For these simulations, orthosteric agonist affinity (1  $\mu$ M),  $\tau_A$  (10), and modulator affinity (10 nM) were held constant, and different magnitudes of positive or negative cooperativity were examined alongside changes in the magnitude of cooperative agonist binding. Consistent with our analysis of mGlu<sub>5</sub> allosteric interaction data, when the agonist binding slope ranged from 1 to 2, the affinity of NAMs and PAMs estimated using the original operational model of agonism and allosterism fell within ~3-fold of the affinity simulated with the operational model of allosterism with cooperative agonist binding. Further, only the affinity of the full NAM (where  $\alpha\beta$  is assumed to approach zero) fell outside this 3-fold window once the agonist binding slope exceeded 2 (Figure 7A). Similarly, when analyzed with the original operational model of agonism and allosterism,  $\alpha\beta$  values (0.1 – 10) were within a 3-fold range of simulated data when  $nT$  ranged from 1 to 2. However, where the magnitude of cooperativity exceeded 10 for a PAM, or 0.1 for a NAM, the influence of cooperative agonist binding becomes more pronounced (Figure 7B). These simulations confirm that the assignment of  $n$  to a transducer or binding slope would not be

MOL # 118091

expected to greatly influence quantification of mGlu<sub>5</sub> allosteric modulation of glutamate for modulators with moderate cooperativity, consistent with our Ca<sup>2+</sup><sub>i</sub> mobilization data.

## Discussion

In the current study, we have assessed operational models of agonism and allosterism that account for receptors whose agonists bind multiple binding sites in a cooperative manner. The modified models accurately fit experimental data at an exemplar GPCR, the CaSR, which has high sensitivity for Ca<sup>2+</sup><sub>o</sub> due to multiple Ca<sup>2+</sup><sub>o</sub> binding sites that are linked in a positively cooperative manner. We show that agonist Hill slopes that differ from unity and remain unchanged by alterations in receptor expression levels or cellular coupling efficiencies (i.e. where  $\tau_A$  differs) may be indicative of cooperative agonist binding. We demonstrate that if a steep Hill slope such as that observed at the CaSR is attributed to the transducer slope rather than to the agonist binding slope, the Black and Leff operational model of agonism underestimates agonist efficacy and overestimates agonist affinity. Extension to allosteric interactions shows the importance of accounting for cooperative agonist binding, as different models fitted to the same allosteric interaction data yield divergent modulator affinity and cooperativity estimates. For instance, the original operational model of agonism and allosterism estimates lower CaSR PAM and NAM cooperativity values, and higher or lower affinity values, respectively. Data simulations support these findings and demonstrate that the impact of cooperative binding on estimates of modulator affinity and cooperativity is more pronounced as the magnitude of modulator cooperativity or cooperative agonist binding is increased. This was evidenced by our demonstration that for mGlu<sub>5</sub>, where the glutamate Hill slope is ~1.8, differences in affinity and cooperativity are within the margin of experimental error (~3-fold range). Accordingly, for agonist-receptor concentration-response relationships with Hill slopes equal to unity, it

MOL # 118091

does not matter whether the slope is governed by the transducer slope or the agonist binding slope.

The operational models of agonism and allosterism with cooperative agonist binding have important practical uses for analyzing data at receptors that possess multiple agonist binding sites. This is particularly true for the CaSR, but also for ion channels and other GPCRs where agonist binding coefficients differ from unity, such as GPR39, which binds at least two  $Zn^{2+}$  ions and responds to  $Zn^{2+}$  with a Hill slope of 2 – 3 (Sato et al., 2016; Storjohann et al., 2008). Similarly, cooperative binding can occur across a GPCR dimer, which may account for the steep Hill slope at mGlu<sub>5</sub> demonstrated in the present study. For instance, the mGlu<sub>2</sub> orthosteric agonist, LY354740, stabilizes conformational rearrangements of a metabotropic glutamate receptor (mGlu) subtype 2 and 4 heterodimer (mGlu<sub>2</sub>-mGlu<sub>4</sub>) with a shallow hill slope (Moreno Delgado et al., 2017), which is increased to unity when LY354740 is prevented from binding to the mGlu<sub>2</sub> or mGlu<sub>4</sub> orthosteric binding site in the dimer. In contrast, glutamate  $E_{max}$  is reduced when it can bind to only one of the orthosteric sites in the heterodimer (Moreno Delgado et al., 2017). These findings indicate negative (LY354740) and positive (glutamate) cooperativity across the dimer, respectively. Negative cooperative binding has also been demonstrated at several class A GPCRs dimers, including the 5-HT<sub>2A</sub>, A<sub>3</sub> adenosine, H<sub>3</sub> histamine and D<sub>2</sub> dopamine receptors (Brea et al., 2009; May et al., 2011; Sinkins and Wells, 1993; Vivo et al., 2006). Accurate quantification of ligand affinity, efficacy and cooperativity at such receptors using functional assays is critical, particularly where radioligand binding based methods are not available. Indeed, there are no commercially available radioligands for the CaSR, thus pharmacological characterization, and indeed drug discovery at this receptor, has generally relied upon functional measures of receptor activity to quantify drug actions. However, it must be noted that experimentally

MOL # 118091

derived pharmacological data for agonists with steep Hill slopes will likely only be fitted to the cooperative agonist operational model and the operational model of allosterism with cooperative agonist binding when one of either the binding or transducer slopes ( $nB$  or  $nT$ ) is known and constrained as such. This was a key advantage of analyzing pharmacological data at the CaSR, where we showed experimentally that the transducer slope is 1.

Our findings have important implications for past and present drug discovery efforts at class C GPCRs and beyond. Establishing SAR profiles that dictate drug affinity and cooperativity is essential for predicting drug efficacy *in vivo*. However, underestimates of cooperativity at class C GPCRs with cooperative agonist binding may explain previous observations that class C GPCR allosteric modulators have limited cooperativity when compared to their class A GPCR counterparts. For example, PAMs with  $\alpha\beta$  values  $>100$  have been reported for class A GPCRs (Abdul-Ridha et al., 2014; Leach et al., 2010), whereas for the CaSR, potentiation is at most 5-fold for many modulators (Cook et al., 2015; Diepenhorst et al., 2018; Leach et al., 2016). Thus, for GPCRs with cooperative agonist binding, larger differences between modulator cooperativities were likely previously unappreciated. This is important because allosteric modulator cooperativity can predict likely clinical efficacy or adverse effect liability. Inaccurate estimation of allosteric modulator affinity or cooperativity due to a failure to consider cooperative agonist binding likely also impacts interpretation of structure-function studies. If cooperativity values are narrowed, then more subtle effects of mutations on modulator cooperativity may have been missed.

In conclusion, we have validated a method for quantifying agonist and allosteric modulator actions at receptors that possess multiple agonist binding sites that interact in a cooperative manner. Our operational models of agonism and allosterism with cooperative agonist binding

MOL # 118091

more accurately quantify the actions of both orthosteric and allosteric drugs acting at GPCRs with cooperative agonist binding and may be used for future drug discovery efforts at these important receptors.

Data are mean + SD from 5 independent experiments performed in duplicate. Curves through the data are the fits to the cooperative agonist operational model, where parameters describing the fits are shown in Table 3.

**Figure 4. Allosteric modulation at the CaSR is fitted well by an operational model of allosterism with cooperative agonist binding.** Allosteric modulation of  $Ca^{2+}_o$ -mediated  $Ca^{2+}_i$  mobilization at the CaSR by NPS2143 (NAM) or cinacalcet (PAM). Data were previously published (Leach et al., 2016) and are mean + SD from at least 11 independent experiments performed in duplicate. Curves through the data are the fits to the operational model of allosterism with cooperative agonist binding and contaminating agonist (Eq 7 for cinacalcet and Eq 8 for NPS2143), where parameters describing the fits are shown in Table 4.

**Figure 5. Allosteric modulation at mGlu<sub>5</sub> is fitted well by an operational model of allosterism with cooperative agonist binding.** Allosteric modulation of glutamate-mediated  $Ca^{2+}_i$  mobilization at mGlu<sub>5</sub> by MPEP (full NAM), M-5MPEP (partial NAM), VU-29 (PAM) and DPFE (ago-PAM). Data were previously published (Sengmany et al., 2019; Sengmany et al., 2017) and are mean + SD from at least 3 independent experiments performed in duplicate previously published. Curves through the data are the fits to the operational model of allosterism with cooperative agonist binding (Eq 4), where parameters describing the fits are shown in Table 5.

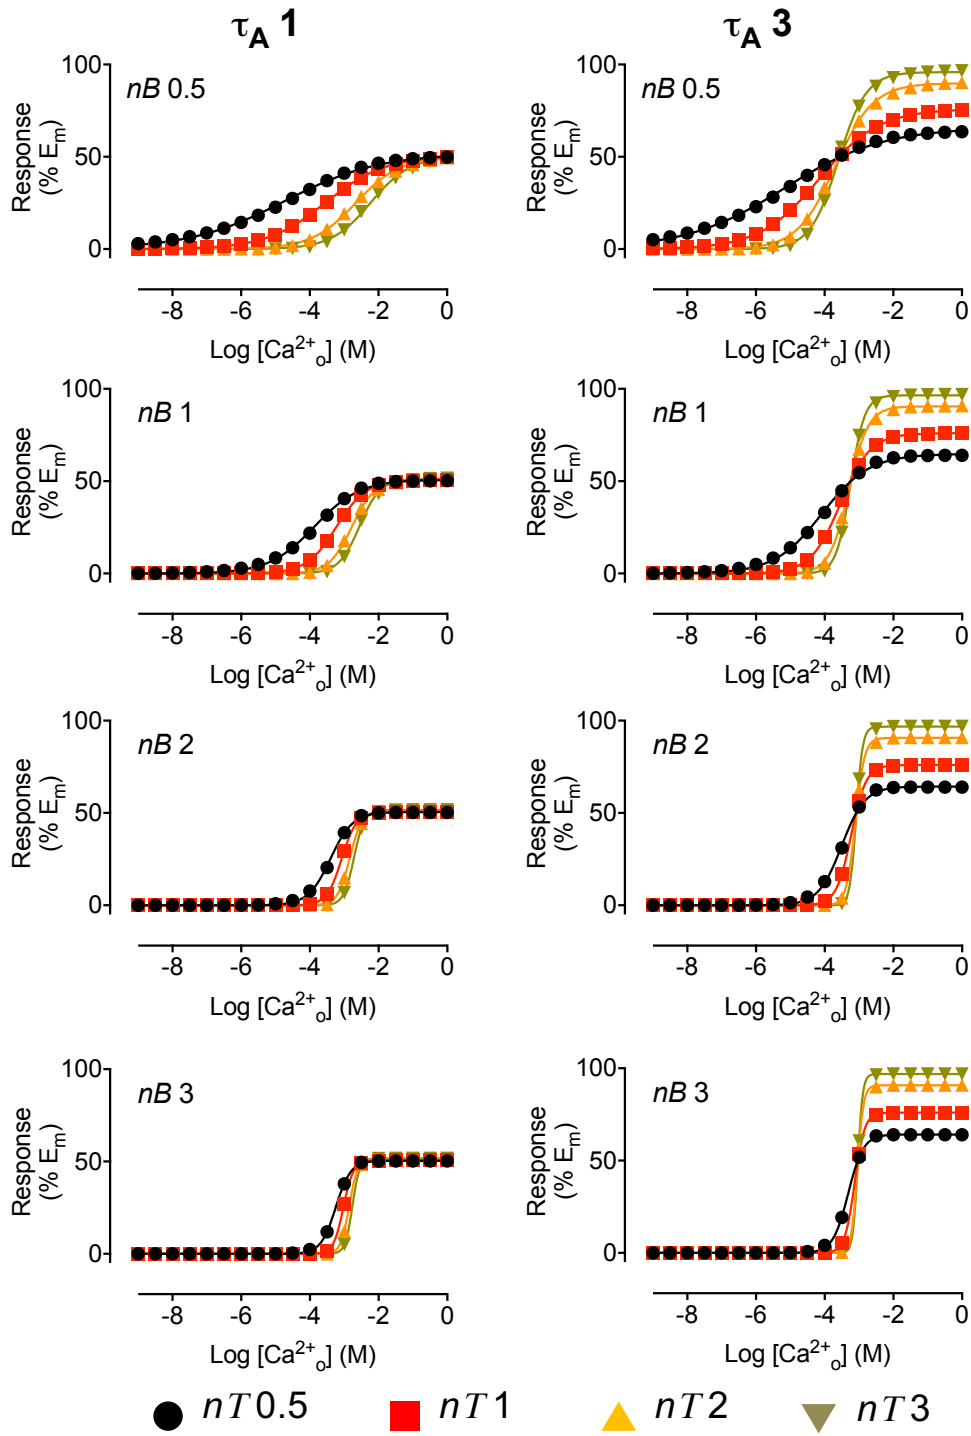

MOL # 118091

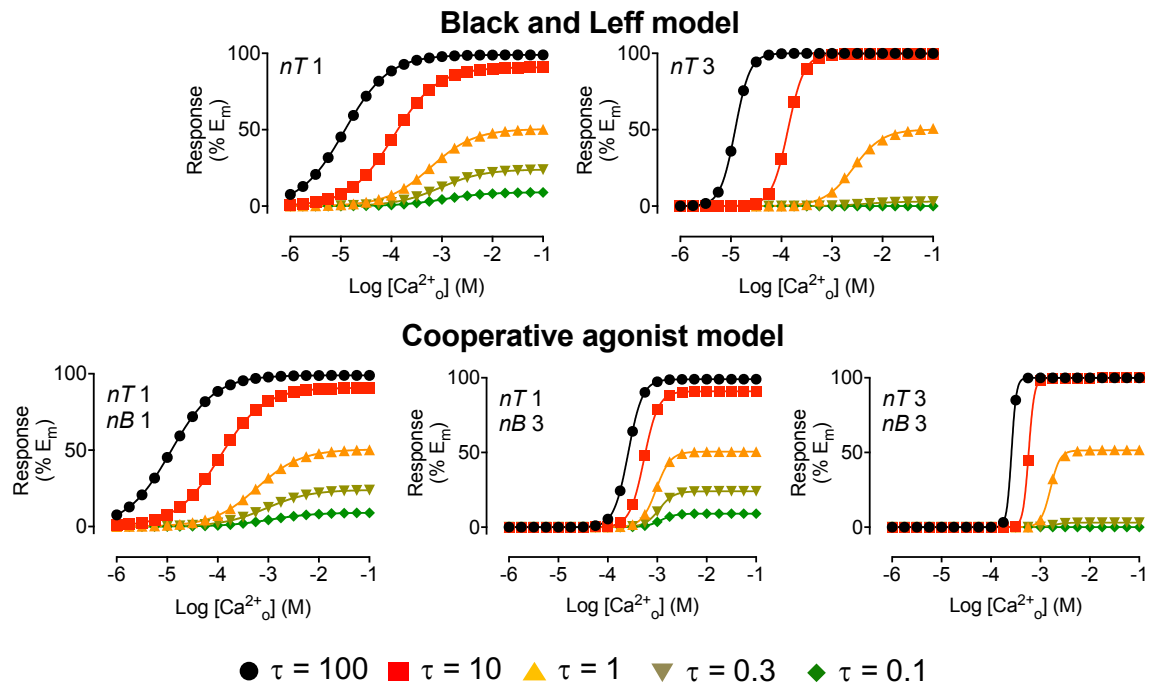

**Figure 6. Allosteric modulation at the M<sub>4</sub> mAChR is fitted well by an operational model of allosterism with no cooperative agonist binding.** Positive modulation of ACh-mediated [<sup>35</sup>S]GTPγS binding by LY2033298 (ago-PAM) at the M<sub>4</sub> mAChR. Data were previously published (Leach et al., 2010) and are mean + SD from at least 3 independent experiments performed in duplicate. Curves through the data are the fits to the operational model of allosterism with cooperative agonist binding (Eq 4), where the Eq was fitted best when n=1 (i.e. no cooperative agonist binding). Parameters describing the fits are shown in Table 6.

**Figure 7. Modulator affinity and cooperativity are influenced by assignment of the slope in the operational model of allosterism.** Simulations demonstrating the influence of the agonist binding slope on estimated modulator affinity and cooperativity when interaction data are analyzed using the original operational model of allosterism. Interaction data between an orthosteric agonist and a NAM or PAM were simulated with the operational model of allosterism with cooperative agonist binding. Orthosteric agonist affinity (1 μM), τ<sub>A</sub> (10), and modulator affinity (10 nM) were held constant, and different magnitudes of positive or negative cooperativity were examined alongside changes in the magnitude of cooperative agonist binding. The simulated data were analyzed with the original operational model of allosterism, and LogK<sub>B</sub> (A) or Logαβ (B) estimates were plotted against the agonist binding slope.

## Appendix

### Cooperative agonist operational model

A model of signal transduction by a receptor with  $n_B$  binding sites is displayed in the equilibrium:

Where  $K_E$  is the value of  $A_{n_B}R$  that elicits half the maximal system effect and agonist affinity for each site can be described by the equilibrium dissociation constants:

$$K_{A1} = \frac{[A][R]}{[AR]}, K_{A2} = \frac{[A][AR]}{[A_2R]}, K_{A3} = \frac{[A][A_2R]}{[A_3R]}, \text{ etc}$$

We see that

$K_{A1} \times K_{A2} \times K_{A3} \times \dots \times K_{A_{n_B}} = \frac{[A]^{n_B}[R]}{[A_{n_B}R]} = K_A^{n_B}$ , where  $K_A$  is the geometric mean of the individual equilibrium dissociation constants.

For simplicity, the receptor is considered either empty ( $R$ ) or fully occupied ( $A_{n_B}R$ ):

$$K_A^{n_B} = \frac{[A]^{n_B}[R]}{[A_{n_B}R]}$$

The total receptor concentration can be expressed as:

$$[R_0] = [R] + [A_{n_B}R]$$

where

$$[R] = \frac{K_A^{n_B}[A_{n_B}R]}{[A]^{n_B}}$$

therefore

$$[R_0] = \frac{K_A^{nB} [A_{nB}R]}{[A]^{nB}} + [A_{nB}R]$$

$$[R_0] = [A_{nB}R] \left( \frac{K_A^{nB}}{[A]^{nB}} + 1 \right)$$

$$[R_0] = [A_{nB}R] \left( \frac{K_A^{nB} + [A]^{nB}}{[A]^{nB}} \right)$$

Receptor occupancy is thus denoted:

$$[A_{nB}R] = \frac{[R_0][A]^{nB}}{K_A^{nB} + [A]^{nB}}$$

In accordance with the scheme of the operational model of agonism, the logistic function for the transduction of occupancy into response is:

$$E = \frac{E_m [A_{nB}R]^{nT}}{K_E^{nT} + [A_{nB}R]^{nT}};$$

where  $nT$  is a logistic slope factor describing the transduction of agonist binding into a response (the transducer slope).

Using the previous expression of  $[A_{nB}R]$  gives:

$$E = \frac{E_m \left( \frac{[R_0][A]^{nB}}{K_A^{nB} + [A]^{nB}} \right)^{nT}}{K_E^{nT} + \left( \frac{[R_0][A]^{nB}}{K_A^{nB} + [A]^{nB}} \right)^{nT}}$$

Multiplying numerator and denominator by  $(K_A^{nB} + [A]^{nB})^{nT}$  gives:

$$E = \frac{E_m [R_0]^{nT} [A]^{nBnT}}{K_E^{nT} (K_A^{nB} + [A]^{nB})^{nT} + [R_0]^{nT} [A]^{nBnT}}$$

Dividing through by  $K_E$  and redefining  $\frac{[R_0]}{K_E}$  as  $\tau_A$  gives an operational model of agonism for a

receptor with  $nB$  binding sites (Eq 2 in the main text):

$$E = \frac{E_m \tau_A^{nT} [A]^{nBnT}}{(K_A^{nB} + [A]^{nB})^{nT} + \tau_A^{nT} [A]^{nBnT}}$$

For use in Graphpad Prism or similar software, the above equation is described by the following notations, where  $nT$  or  $nB$  will likely need to be fixed to a known or theoretical value to fit real experimental data to this equation, and where a “Basal” response parameter is introduced to accommodate ligand-independent effects that deviate from zero:

$$KA = 10^{\text{LogKA}}$$

$$A = 10^X$$

$$\text{tau} = 10^{\text{Logtau}}$$

$$\text{Part1} = (E_m - \text{Basal}) * \text{tau} * (A^{nB})$$

$$\text{Part2} = \text{tau} * (A^{nB}) + (A^{nB}) + (KA^{nB})$$

$$Y = \text{Basal} + (\text{Part1}^{nT}) / (\text{Part2}^{nT})$$

## Operational model of allosterism with cooperative agonist binding

In a ternary complex consisting of a receptor (lacking constitutive activity), an orthosteric agonist that binds  $n_B$  binding sites, and an allosteric modulator, the stimulus-generating species are  $A_{n_B}R$ ,  $BR$  and  $A_{n_B}RB$ . A model of ligand-receptor interactions in this ternary complex is displayed in the equilibrium:

where

$$K_A^{n_B} = \frac{[A]^{n_B}[R]}{[A_{n_B}R]}, K_B = \frac{[B][R]}{[BR]}, \text{ and } \frac{K_B}{\alpha} = \frac{[A_{n_B}R][B]}{[A_{n_B}RB]}$$

From the latter expression we obtain:

$$\alpha = \frac{K_B[A_{n_B}RB]}{[A_{n_B}R][B]}$$

Assuming the pharmacological effect ( $E$ ) is a function of the total stimulus ( $S_T$ ) arising from the sum of the stimuli generated from each individual ligand-bound receptor species, then:

$$S_T = S_{A_{n_B}R} + S_{BR} + S_{A_{n_B}RB}$$

It is further assumed that the stimulus ( $S$ ) generated from each individual ligand-bound receptor species is proportional to the product of the intrinsic efficacy of the ligand ( $\epsilon$ ) and the concentration of the ligand-bound receptor species, thus:

$$S_{A_{n_B}R} = \epsilon_{A_{n_B}}[A_{n_B}R]; S_{BR} = \epsilon_B[BR]; S_{A_{n_B}RB} = \epsilon_{A_{n_B}B}[A_{n_B}RB]; \text{ and } \epsilon_{A_{n_B}B} = \beta\epsilon_{A_{n_B}}$$

where  $\varepsilon_{A_{nB}}$  denotes the intrinsic efficacy of the orthosteric agonist,  $\varepsilon_B$  denotes the intrinsic efficacy of the allosteric modulator, and  $\beta$  is a coupling factor that describes the effect of the allosteric modulator on the intrinsic efficacy of the orthosteric agonist when the two ligands are bound to the same receptor.

Thus, the effect (E) of an agonist in the presence of an allosteric modulator is processed through the following logistic equation

$$E = \frac{E_m S_T^{nT}}{K_S^{nT} + S_T^{nT}}$$

where  $E_m$  denotes the maximum possible response,  $K_S$  denotes a constant that governs the efficiency of stimulus-response coupling and  $nT$  denotes a logistic slope factor (the transducer slope).

If we consider the total receptor concentration:

$$[R_0] = [R] + [A_{nB}R] + [BR] + [A_{nB}RB]$$

where

$$[A_{nB}R] = \frac{[R_0][A]^{nB}}{[A]^{nB} \left(1 + \frac{\alpha[B]}{K_B}\right) + K_A^{nB} \left(1 + \frac{[B]}{K_B}\right)};$$

$$[BR] = \frac{[R_0][B]}{[B] \left(1 + \frac{\alpha[A]^{nB}}{K_A^{nB}}\right) + K_B \left(1 + \frac{[A]^{nB}}{K_A^{nB}}\right)}$$

and

$$[A_{nB}RB] = \frac{[R_0][A]^{nB}}{[A]^{nB} \left(1 + \frac{K_B}{\alpha[B]}\right) + K_A^{nB} \left(\frac{1}{\alpha} + \frac{K_B}{\alpha[B]}\right)} ;$$

substituting the above terms into  $E = \frac{E_m S_T^{nT}}{K_S^{nT} + S_T^{nT}}$  gives the following operational model of allosterism at a receptor with nB orthosteric agonist binding sites (Eq 4 in the main text):

$$E = \frac{E_m (\tau_A [A]^{nB} (K_B + \alpha\beta[B]) + \tau_B [B] [K_A]^{nB})^{nT}}{([A]^{nB} K_B + K_A^{nB} K_B + K_A^{nB} [B] + \alpha [A]^{nB} [B])^{nT} + (\tau_A [A]^{nB} (K_B + \alpha\beta[B]) + \tau_B [B] K_A^{nB})^{nT}}$$

where

$$\tau_A = \frac{\varepsilon_{A_{nB}} [R_0]}{K_S}$$

and

$$\tau_B = \frac{\varepsilon_B [R_0]}{K_S}$$

For use in Graphpad Prism or similar software, the above equation is described by the following notations, where nT or nB will likely need to be fixed to a known or theoretical value to fit real experimental data to this equation:

$$KA = 10^{\text{Log}KA}$$

$$KB = 10^{\text{Log}KB}$$

$$\text{tau}A = 10^{\text{Log} \text{tau}A}$$

$$\text{tau}B = 10^{\text{Log} \text{tau}B}$$

$$A = (10^X)$$

$$\text{alpha} = 10^{\text{Log} \text{alpha}}$$

$$\text{beta} = 10^{\text{Log} \text{beta}}$$

$$B = 10^{\text{Log} \text{Allo}}$$

$$\text{Part}1 = \text{tau}A * (A^{nB}) * (KB + \text{alpha} * \text{beta} * B) + \text{tau}B * B * (KA^{nB})$$

$$\text{Part2}=(A^{nB})\cdot K_B+(K_A^{nB})\cdot K_B+B\cdot(K_A^{nB})+\alpha\cdot(A^{nB})\cdot B$$

$$\text{Stim}=\text{Part1}/\text{Part2}$$

$$Y=\text{Basal}+((E_m-\text{Basal})\cdot(\text{Stim}^{nT}))/((\text{Stim}^{nT})+(1^{nT}))$$

For the purposes of the current study, the model has been simplified further to enable analysis of data when the orthosteric agonist is a full agonist. Therefore, equation 4 in the manuscript reduces to:

$$E=\frac{E_m(\tau_A[A]^{nB}(K_B+\alpha\beta[B])+\tau_B[B]K_A^{nB})^{nT}}{K_A^{nBnT}(K_B+[B])^{nT}+(\tau_A[A]^{nB}(K_B+\alpha\beta[B])+\tau_B[B]K_A^{nB})^{nT}}$$

Dividing through by  $\tau_A^{nT}$ , and defining  $[EC_{50}]=K_A/\tau_A$  yields the following expression:

$$E=\frac{E_m([A]^{nB}(K_B+\alpha\beta[B])+\tau_B[B][EC_{50}]^{nB})^{nT}}{[EC_{50}]^{nBnT}(K_B+[B])^{nT}+([A]^{nB}(K_B+\alpha\beta[B])+\tau_B[B][EC_{50}]^{nB})^{nT}}$$

“Evaluation of operational models of agonism and allosterism at receptors with multiple orthosteric binding sites”

**Supplemental Data**

**Supplemental Figure 1: Cell surface expression levels of WT and N terminally truncated CaSR.** Cell surface expression + SD was determined via FACS analysis as described in the methods section.

**Supplemental Figure 2: Concentration-response relationships for endogenous agonists at three different GPCRs.** ACh acting at the M<sub>4</sub> mACh receptor (blue) has a Hill coefficient equal to 1. Glutamate acting at mGlu<sub>5</sub> (red) has a Hill coefficient of ~1.8, whereas Ca<sup>2+</sup><sub>o</sub> acting at the CaSR (black) has Hill coefficients ranging from 2-4. Data + SD are replotted from (Leach et al., 2016; Leach et al., 2010; Sengmany et al., 2016).
