ABSTRACT
Tumors provide an extremely abnormal microenvironment that stimulates neovascularization from surrounding vessels and causes altered gene expression within vascular cells. Up-regulation of vascular endothelial growth factor (VEGF) receptors has allowed selective destruction of tumor vessels by administration of a chimeric protein consisting of VEGF121 coupled to the toxin gelonin (VEGF/rGel). We sought to determine whether there is sufficient up-regulation of VEGF receptors in endothelial cells participating in ocular neovascularization to permit a similar strategy. After intravenous injection of 45 mg/kg VEGF/rGel, but not uncoupled recombinant gelonin (rGel), there was immunofluorescent staining for rGel within choroidal neovascularization in mice and regression of the neovascularization occurred, demonstrating successful vascular targeting via the systemic circulation. Intraocular injection of 5 ng of VEGF/rGel also caused significant regression of choroidal neovascularization in two models, transgenic mice with expression of VEGF in photoreceptors and mice with ischemic retinopathy, whereas injection of 5 ng of rGel had no effect. These data suggest that the strategy of vascular targeting can be applied to nonmalignant neovascular diseases and could serve as the basis of a new treatment to reduce established ocular neovascularization.

As tumors grow, they become hypoxic, causing increased production of VEGF and other hypoxia-regulated gene products (Plate et al., 1992; Shweiki et al., 1992). Angiogenesis is stimulated from surrounding host vessels, and the new vessels invade and vascularize the tumor. Despite vascularization and elimination of some of the hypoxia, tumors provide a very abnormal environment for their vasculature. Tumors release several vasoactive substances and disturb cell-cell and cell-matrix interactions. Tumor cells may become incor-
Walter et al., 2001), and proteomic analyses (Schnitzer, 1998; Oh et al., 2004), has greatly expanded the list of potential markers for tumor vasculature.

Differentially expressed gene products provide a means to direct therapeutic agents to tumor vasculature, a strategy that is commonly referred to as “vascular targeting” (Denekamp, 1984, 1999; Thorpe, 2004). Tumor vessel markers that have been exploited and demonstrated to have therapeutic potential in tumor models include (but are not limited to) $\alpha_\beta_5$ and $\alpha_\beta_3$ integrins (Pasqualini et al., 1997), VEGF receptors (Ramakrishnan et al., 1996; Arora et al., 1999; Veenendaal et al., 2002; Liu et al., 2003), the ED-B domain of fibronectin (Nilsson et al., 2001), cellular adhesion molecule-1 (Ran et al., 1998), and prostate-specific membrane antigen (Liu et al., 2002).

Endothelial cells participating in angiogenesis in disease processes other than tumors also display differential gene expression. For example, there is substantial up-regulation of $\alpha_\beta_3$ in ischemia-induced retinal neovascularization (Luna et al., 1996). However, ocular neovascularization may not differ from normal vessels to the same degree as tumor vasculature, and it is not known whether the strategy of vascular targeting can be applied to ocular neovascularization. In this study, we tested in several models of ocular neovascularization the effects of systemic or intraocular administration of a VEGF$_{165}$/gelonin chimeric protein (VEGF/rGel), which has previously been shown to cause infarction of tumor vessels (Veenendaal et al., 2002).

Materials and Methods

Materials. The fusion toxin VEGF/rGel and recombinant gelonin (rGel) were expressed in bacterial cultures, purified to homogeneity, and characterized for biological activity as described previously (Veenendaal et al., 2002). The fusion toxin and rGel were stored in phosphate-buffered saline (PBS) at $-20^\circ$C.

Model of Choroidal Neovascularization. Mice were treated in accordance with the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research and the National Institutes of Health Guide for the Care and Use of Laboratory Animals. The model of laser-induced choroidal neovascularization has been described previously (Tobe et al., 1998b). In brief, 4- to 6-week-old female C57BL/6j mice were anesthetized with ketamine hydrochloride (100 mg/kg b.wt.) and xylazine hydrochloride (20 mg/kg), and pupils were dilated with 1% tropicamide. A 532-nm diode laser ride (100 mg/kg b.wt.) and xylazine hydrochloride (20 mg/kg), and female C57BL/6j mice were anesthetized with ketamine hydrochloride (154 mg/kg VEGF/rGel (eight mice) or rGel (eight mice), or PBS vehicle (seven mice). One week later, they were perfused with fluorescein-labeled dextran, and choroidal neovascularization was measured on choroidal flat mounts. To test the effect of intravitreous administration of VEGF/rGel, nine mice were given an intravitreous injection of 5 ng of rGel in one eye and PBS in the other eye, and 13 mice were given 5 ng of VEGF/rGel in one eye and PBS in the other eye. After 1 week, mice were perfused with fluorescein-labeled dextran, and choroidal neovascularization was measured on choroidal flat mounts.

The fusion toxin VEGF/rGel and recombinant gelonin (rGel) were expressed in bacterial cultures, purified to homogeneity, and characterized for biological activity as described previously (Veenendaal et al., 2002). The fusion toxin and rGel were stored in phosphate-buffered saline (PBS) at $-20^\circ$C.

Model of Choroidal Neovascularization. Mice were treated in accordance with the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research and the National Institutes of Health Guide for the Care and Use of Laboratory Animals. The model of laser-induced choroidal neovascularization has been described previously (Tobe et al., 1998b). In brief, 4- to 6-week-old female C57BL/6j mice were anesthetized with ketamine hydrochloride (100 mg/kg b.wt.) and xylazine hydrochloride (20 mg/kg), and pupils were dilated with 1% tropicamide. A 532-nm diode laser photocoagulator (OcuLight GL; Iridex, Mountain View, CA) with a slit lamp delivery system was used with a coverslip as a contact lens to visualize the retina and deliver sufficient laser energy (75-mW spot size, 0.1-s duration, 140 mW) to rupture Bruch’s membrane in three locations in each eye, the 9, 12, and 3 o’clock positions of the posterior pole. Production of a bubble at the time of laser burn, which indicates rupture of Bruch’s membrane, is an important factor in obtaining reproducible results (Tobe et al., 1998b); therefore, only burns in which a bubble was produced were included in the study.

One week after rupture of Bruch’s membrane, seven mice were anesthetized and perfused with fluorescein-labeled dextran (2 x 10$^6$ average mol. wt.; Sigma-Aldrich, St. Louis, MO), and the amount of choroidal neovascularization at Bruch’s membrane rupture sites was measured on choroidal flat mounts. Other mice received experimental or control injections 1 week after rupture of Bruch’s membrane, and choroidal neovascularization was assessed 1 week later. To test the effect of intravenous administration of VEGF/rGel, mice were given tail vein injections (every 2 days for a total of four injections) of 45 mg/kg VEGF/rGel (eight mice) or rGel (eight mice), or PBS vehicle alone (seven mice). One week later, they were perfused with fluorescein-labeled dextran, and choroidal neovascularization was measured on choroidal flat mounts. To test the effect of intravitreous administration of VEGF/rGel, nine mice were given an intravitreous injection of 5 ng of rGel in one eye and PBS in the other eye, and 13 mice were given 5 ng of VEGF/rGel in one eye and PBS in the other eye. After 1 week, mice were perfused with fluorescein-labeled dextran, and choroidal neovascularization was measured on choroidal flat mounts.

Quantification of Neovascularization on Flat Mounts. In mice with laser-induced choroidal neovascularization, the neovascularization was measured on choroidal flat mounts; and in rho/VEGF transgenics, subretinal neovascularization was measured on retinal flat mounts. Flat mounts were prepared as described previously (Tobe et al., 1998a; Nambu et al., 2003). After mice were terminally perfused with fluorescein-labeled dextran, the eyes were removed and fixed for 1 h in 10% phosphate-buffered formalin, and the cornea and lens were removed. The entire retina was carefully dissected from the eye cup, and depending upon the model, the retina or choroid was flat mounted in Aquamount (Vector Laboratories, Burlingame, CA) after four radial cuts were made in each quadrant. Flat mounts were examined by fluorescence microscopy using an Axioskop II microscope (Carl Zeiss Inc., Thornwood, NY) and captured with a Cool Snap-Pro digital color camera (Photometrics, Tucson, AZ). Retinas were mounted with photoreceptor side up and examined with 400× magnification, which provides a narrow depth of field so that when focusing on the outer edge of the retina, the retinal vessels are out of focus in the background, allowing easy delineation of the subretinal neovascularization. Image-Pro Plus software (Media Cybernetics, Inc., Silver Spring, MD) was used to measure the area of each subretinal or choroidal neovascularization lesion.

Quantitative Real-Time Reverse Transcription-Polymerase Chain Reaction. Adult C57BL/6j mice had laser-induced rupture of Bruch’s membrane in three locations in one eye, and the contralateral eye served as control. After 1 week, mice were euthanized, and the eyes were removed. Anterior segments and retinas were removed and eye cups, which contain the choroid, were snap frozen by placing them into a mortar precooled with liquid nitrogen. They were then crushed, and the frozen powder was transferred into 1.5-ml tubes filled with 0.6 ml of lysis buffer. Rho/VEGF transgenic mice and littermate controls were euthanized at P16, and retinas, choroids, and lens were removed and placed in lysis buffer. After 1 week, mice were perfused with fluorescein-labeled dextran, and choroidal neovascularization was measured on choroidal flat mounts. To test the effect of intravitreous injection of 5 ng of rGel in one eye and PBS in the other eye, and 13 mice were given 5 ng of VEGF/rGel in one eye and PBS in the other eye. After 1 week, mice were perfused with fluorescein-labeled dextran, and choroidal neovascularization was measured on choroidal flat mounts.

RNA isolation was performed using a RNAsasy kit (QIAGEN, Valencia, CA). To remove any contaminating genomic DNA, RNA samples were treated with DNase I (Invitrogen, Carlsbad, CA) at room temperature for 15 min, and then cDNA was synthesized with reverse transcriptase (SuperScript III; Invitrogen) and 5 μM random hexamer. Real-time quantitative PCR was performed and analyzed on the MJ Research Chromo4 thermal cycler system (MJ Research, Watertown, MA) using the SYBR Green 1 format. Reactions were performed in a 20-μl volume using the SYBR Green reaction mixture (QIAGEN) with 0.5 mM primers. 28S rRNA was used as a standard for normalization. The sequences of the PCR primer pairs were 1) VEGF receptor 2, 5′-CAT CGT CCA CGC CTG CAA-3′ (forward) and 5′-GCT TGG TGC CGC CTA-3′ (reverse); and 2) 28S, 5′-TGG AAA ATC CGG GGG AGA G-3′ (forward) and 5′-ACA TTG TTC CAA CAT GCC AG-3′ (reverse). Murine cDNAs for VEGF receptor 2 and...
28S rRNA were synthesized by RT-PCR from mouse retinal RNA using *Pfu Taq* polymerase (Stratagene, La Jolla, CA). The PCR products were purified with a QIAGEN gel extraction kit and used to generate standard curves for each gene for each real-time PCR reaction. Standard curves were used to calculate mRNA copy numbers for each retinal RNA sample, and target gene mRNA copy numbers were normalized to 10^7 copies of 28S.

**Immunofluorescent Localization of VEGF/rGel.** One week after rupture of Bruch’s membrane, mice were given 45 mg/kg VEGF/rGel or rGel, or vehicle alone by tail vein injection. Forty-five minutes later, mice were given an intraperitoneal injection of 300 U of heparin and 15 min later, mice were terminally perfused by pumping saline into the left ventricle at 1 ml/min for 12 min. The eyes were removed and frozen in optimum cutting temperature embedding compound (Bayer Corp., Emeryville, CA). Frozen sections were cut, and adjacent sections were stained with biotinylated *Griffonia simplicifolia* lectin B4 (GSA), which selectively stains vascular cells, or with 10 μg/ml rabbit anti-rGel antibody (Veendael et al., 2002). Rabbit anti-rGel antibody was detected with goat anti-rabbit IgG conjugated to fluorescein isothiocyanate (Jackson ImmunoResearch Laboratories Inc., West Grove, PA).

**Histochemical Staining with GSA Lectin.** Slides were incubated in methanol/H2O2 for 10 min at 4°C, washed with 0.05 M TBS, and incubated for 30 min in 10% normal porcine serum (NPS). Slides were incubated 2 h at room temperature with 1:20 biotinylated GSA lectin (Vector Laboratories) in TBS/1% NPS, and after rinsing with 0.05 M TBS, they were incubated with 1:10 avidin coupled to peroxidase (Vector Laboratories) in TBS/1% NPS for 45 min at room temperature. After a 10-min wash in 0.05 M TBS, slides were incubated with diaminobenzidine (Research Genetics, Huntsville, AL) to produce a brown reaction product.

**Mice with Oxygen-Induced Ischemic Retinopathy.** Ischemic retinopathy was produced by a method described previously (Smith et al., 1994). At P7, litters of mice were placed in an airtight incubator and exposed to an atmosphere of 75 ± 3% oxygen for 5 days. Incubator temperature was maintained at 23 ± 2°C, and oxygen was measured every 8 h with an oxygen analyzer. After 5 days, the mice were removed from the incubator and placed in room air. At P17, six mice were euthanized to measure the baseline amount of neovascularization, and seven mice were given an intravitreal injection of 5 ng of VEGF/rGel in one eye and 5 ng of rGel in the other eye. At P21, mice were euthanized to measure retinal neovascularization.

**Measurement of Retinal Neovascularization in Mice with Ischemic Retinopathy.** After euthanasia, eyes were rapidly removed and frozen in optimum cutting temperature embedding compound. Ocular frozen sections (10 μm) were histochemically stained with GSA as described above. Slides were counterstained with eosin, which stains the internal limiting membrane, and mounted (Cytoseal; Stephens Scientific, Cornwall, NJ). To perform quantitative assessments, 10-μm serial sections were cut through the entire eye,

![Fig. 2. Localization of VEGF/rGel in choroidal neovascularization after intravenous injection.](image-url)
starting with sections that included the iris root on one side of the eye and proceeding to the iris root on the other side. Every 10th section, roughly 100 μm apart, was stained with GSA, and images were digitized with a three-CCD color video camera and a frame grabber. Image analysis was used to delineate GSA-stained cells on the surface of the retina, and their area was measured. The mean area of neovascularization per section was calculated for each eye and was used as a single experimental value.

Statistical Analyses. Statistical comparisons were made using a linear mixed model (Verbeke and Molenberghs, 2000). This model is analogous to analysis of variance, but it allows analysis of all choroidal neovascularization area measurements from each mouse rather than average choroidal neovascularization area per mouse by accounting for correlation between measurements from the same mouse. The advantage of this model over analysis of variance is that it accounts for differing precision in mouse-specific average measurements arising from a varying number of observations among mice.

Results

VEGF Receptor 2 Is Up-Regulated in Choroidal and Subretinal Neovascularization. Seven days after rupture of Bruch’s membrane in several locations, C57BL/6 mice were euthanized, and total RNA was isolated from the eye-cup. Compared with contralateral eyes that did not receive laser, quantitative RT-PCR demonstrated a significant increase in VEGF receptor 2 mRNA in the retina/choroid of mice with choroidal neovascularization (Fig. 1). Mice that carry a rhodopsin promoter/VEGF transgene spontaneously develop subretinal neovascularization (Okamoto et al., 1997).

Fig. 3. Intravenous injection of VEGF/rGel causes regression of choroidal neovascularization. Thirty adult C57BL/6 mice had laser-induced rupture of Bruch’s membrane in three locations in each eye. After 1 week, seven mice were perfused with fluorescein-labeled dextran, and the baseline amount of choroidal neovascularization at rupture sites (Fig. 3A, arrows) was measured by image analysis of choroidal flat mounts. The remaining mice received tail vein injections every 2 days (four injections) of 45 mg/kg rGel or VEGF/rGel, or PBS. One week after the start of injections, the mice were perfused with fluorescein-labeled dextran, and choroidal flat mounts were examined by fluorescence micro-

Compared with littermate transgene-negative controls, transgenic mice with subretinal neovascularization showed a large increase in VEGF receptor 2 mRNA (Fig. 1). VEGF/rGel Localizes to Choroidal Neovascularization after Intravenous Injection. Seven days after laser-induced rupture of Bruch’s membrane, mice were given 45 mg/kg rGel or VEGF/rGel, or vehicle alone by tail vein injection. After 1 h, the mice were euthanized, and ocular sections were histochemically stained with GSA or immunofluorescently stained with anti-gelonin antibody. Mice that had received an injection of PBS or rGel showed choroidal neovascularization at Bruch’s membrane rupture sites (Fig. 2, A and C, arrows) that did not stain for gelonin (Fig. 2, B and D, arrows). In contrast, mice that had received an intravenous injection of VEGF/rGel showed staining for gelonin within choroidal neovascularization (Fig. 2, E and F, arrows).

Intravenous Injection of VEGF/rGel Causes Regression of Choroidal Neovascularization. Thirty adult C57BL/6 mice had laser-induced rupture of Bruch’s membrane at three locations in each eye. After 1 week, seven mice were perfused with fluorescein-labeled dextran, and the baseline amount of choroidal neovascularization at rupture sites (Fig. 3A, arrows) was measured by image analysis of choroidal flat mounts. The remaining mice were divided into three groups: eight mice received a tail vein injection of 45 mg/kg rGel every 2 days for a total of four injections (B), seven mice received a tail vein injection of PBS every 2 days (C), and eight mice received a tail vein injection of 45 mg/kg VEGF/rGel every 2 days (D). After 1 week, the mice were perfused with fluorescein-labeled dextran, and choroidal flat mounts were examined by fluorescence microscopy. The area of choroidal neovascularization at rupture sites appeared substantially smaller in mice that had been injected with VEGF/rGel (D, arrows) than that in mice that had been injected with rGel (B, arrows) or PBS (C, arrows). It was also smaller than the amount of choroidal neovascularization seen at baseline (A). Image analysis confirmed that the area of choroidal neovascularization was significantly smaller 1 week after injection of VEGF/rGel compared with baseline (E). †, p = 0.0003 for difference from baseline by linear mixed model. †, p < 0.0001 for difference from gelonin by linear mixed model. Scale bar, 100 μm.
copy. The area of choroidal neovascularization (square millimeters \( \times 10^{-2} \)) at rupture sites seemed smaller in mice that had been injected with VEGF/rGel (0.95 \pm 0.20; Fig. 3D, arrows) compared with those in mice that had been injected with rGel (2.25 \pm 0.30; Fig. 3B, arrows) or PBS (2.65 \pm 0.48; Fig. 3C, arrows), and a statistically significant difference was confirmed by image analysis (Fig. 3E). They were also smaller than baseline choroidal neovascularization lesions present on day 7 (1.56 \pm 0.14; Fig. 3, A and E), indicating that VEGF/rGel caused regression of choroidal neovascularization.

**Intravitreous Injection of VEGF/rGel Causes Regression of Choroidal Neovascularization.** Thirty-one adult C57BL/6 mice had laser-induced rupture of Bruch’s membrane in three locations in each eye. After 1 week, nine mice were perfused with fluorescein-labeled dextran, choroidal flat mounts were prepared, and the baseline amount of choroidal neovascularization at rupture sites (Fig. 4A) was measured. The remaining mice were divided into two groups; nine mice received an intravitreous injection of 5 ng of rGel in one eye and PBS in the other eye, and 13 mice received 5 ng of VEGF/rGel in one eye and PBS in the other eye. After 1 week, the mice were perfused with fluorescein-labeled dextran, and choroidal flat mounts were examined by fluorescence microscopy. The area of choroidal neovascularization (square millimeters \( \times 10^{-2} \)) at rupture sites was less in mice that had been injected with VEGF/rGel (0.43 \pm 0.07; Fig. 4, D, arrows, and E) compared with that in mice that had been injected with rGel (1.03 \pm 0.17; Fig. 4B, arrows) or PBS (0.92 \pm 0.20; Fig. 4C, arrows). It was also smaller than the amount of choroidal neovascularization seen at baseline (1.19 \pm 0.19; Fig. 4A).

**Intravitreous Injection of VEGF/rGel Causes Regression of Neovascularization in Rhodopsin/VEGF Transgenic Mice.** Transgenic mice in which the rhodopsin promoter drives expression of VEGF in photoreceptors (rho/VEGF mice) develop subretinal neovascularization that is quite consistent among mice of the same line in the same genetic background and is easily quantified by image analysis of retinal flat mounts after perfusion of mice with fluorescein-labeled dextran (Okamoto et al., 1997; Tobe et al., 1998a). Eight hemizygous rho/VEGF mice in a C57BL/6 background had the baseline amount of neovascularization per retina (square millimeters \( \times 10^{-3} \)) measured at P21 (Fig. 5A; 10.8 \pm 1.7). The remainder of the transgenic mice (n = 9) received an intravitreous injection of 5 ng of rGel in one eye and 5 ng of VEGF/rGel in the other eye at P21. At P25, compared with the baseline area of neovascularization per retina in VEGF/rGel mice (Fig. 5C; 2.80 \pm 0.98) was significantly less (Fig. 5D). It was also significantly less than the area of neovascularization per retina seen in rGel-injected mice (Fig. 5, B and D; 8.81 \pm 1.94).

---

**Fig. 4.** Intravitreous injection of VEGF/rGel causes regression of choroidal neovascularization. Thirty-one C57BL/6 mice had laser-induced rupture of Bruch’s membrane at three locations in each eye. After 1 week, nine mice were perfused with fluorescein-labeled dextran, and the baseline amount of choroidal neovascularization at rupture sites was measured by image analysis of choroidal flat mounts. The remaining mice were divided into two groups; nine mice received an intravitreous injection of 5 ng of rGel in one eye and PBS in the other eye, and 13 mice received 5 ng of VEGF/rGel in one eye and PBS in the other eye. After 1 week, the mice were perfused with fluorescein-labeled dextran, and choroidal flat mounts were examined by fluorescence microscopy. There was a substantial amount of baseline choroidal neovascularization at 7 days after injection of Bruch’s membrane (A, arrows). At day 14, 7 days after injection of rGel (B, arrows) or PBS (C, arrows), the area of choroidal neovascularization at rupture sites appeared similar to that seen at baseline (A). The amount of choroidal neovascularization seen 7 days after injection of VEGF/rGel (D, arrows) appeared to be less than that seen after injection of rGel or PBS, and less than that seen at baseline. Image analysis confirmed that the area of choroidal neovascularization was significantly smaller 1 week after injection of VEGF/rGel compared with injection of rGel or PBS, or the baseline amount (E). *, \( p = 0.0009 \) for difference from baseline by linear mixed model. †, \( p = 0.0002 \) for difference from gelonin by linear mixed model. Scale bar, 100 \( \mu \text{m} \).
Intravitreous Injection of VEGF/rGel Causes Regression of Ischemia-Induced Retinal Neovascularization.

Mice with oxygen-induced ischemic retinopathy have retinal neovascularization on the surface of the retina similar to that seen in patients with proliferative diabetic retinopathy or retinopathy of prematurity. In this model, the amount of neovascularization is fairly stable between P17 and P21 and then regresses spontaneously. There was prominent neovascularization on the surface of the retina at P17 (Fig. 6, A and B). Eyes that received an intravitreous injection of rGel at P17 still showed substantial neovascularization on the surface of the retina at P21 (Fig. 6, C and D, arrows). However, mice that had been injected with VEGF/rGel at P17 showed almost no identifiable neovascularization at P21 (Fig. 6, E and F). Image analysis demonstrated that VEGF/rGel-injected mice had significantly less neovascularization (0.93 ± 0.25 mm² × 10⁻²) than mice injected with rGel (5.01 ± 0.46), and significantly less than the baseline amount seen at P17 before injection (6.53 ± 0.42, Fig. 6G), indicating that VEGF/rGel induced regression of the retinal neovascularization.

Discussion

Striking regression of tumors has been achieved in several mouse models by systemic injection of chimeric proteins consisting of a toxin coupled to a homing protein that binds to a gene product that is differentially expressed in tumor vasculature (Ramakrishnan et al., 1996; Pasqualini et al., 1997; Ran et al., 1998; Arora et al., 1999; Nilsson et al., 2001; Veenendaal et al., 2002; Liu et al., 2002, 2003). In this study, we have shown that there is up-regulation of VEGF receptor 2 in subretinal or choroidal neovascularization, allowing the same strategy to be used to treat these benign disease processes. Systemically injected VEGF/rGel localizes to choroidal neovascularization and causes significant regression of the neovascularization. As a relatively confined compartment, the eye also affords a modified approach in which VEGF/rGel is injected into the vitreous cavity. In three different models of ocular neovascularization—laser-induced rupture of Bruch’s membrane, rho/VEGF transgenic mice, and oxygen-induced ischemic retinopathy—intravitreous injection of VEGF/rGel, but not injection of rGel, resulted in significant regression of neovascularization. Minimizing systemic exposure is a potential advantage and compared with systemic administration, intravitreous injection reduced the amount of VEGF/rGel required for treatment by approximately 1.8 × 10⁵-fold, another significant advantage, because production and purification of clinical grade recombinant proteins are expensive.
Ocular neovascularization is one of the most prevalent causes of visual morbidity in developed countries. Retinal neovascularization occurs in ischemic retinopathies such as diabetic retinopathy, and it is a major cause of visual loss in working age patients (Klein et al., 1984). Choroidal neovascularization occurs as a complication of age-related macular degeneration and is a major cause of visual loss in elderly patients. Improved treatments are needed to reduce the high rate of visual loss, and their development is likely to be facilitated by greater understanding of the molecular pathogenesis of ocular neovascularization. Several lines of evidence have suggested that VEGF is an important stimulator for both retinal and choroidal neovascularization (Adamis et al., 1994; Aiello et al., 1994, 1995; Seo et al., 1999; Kwak et al., 2000; Ozaki et al., 2000; Saishin et al., 2003). This has led to clinical trials testing the effect of VEGF antagonists in patients with subfoveal choroidal neovascularization. Intraocular injections of pegaptanib, an aptamer that binds VEGF, every 6 weeks for 1 year reduced loss of vision compared with sham injections (Gragoudas et al., 2004). Slowing visual loss is an important achievement, but it is not the ultimate goal, which is to improve vision and/or maintain it within a range that permits optimal functioning.

In animal models, VEGF antagonists are very good at suppressing growth of neovascularization and reducing excessive leakage (Adamis et al., 1996; Aiello et al., 1995; Seo et al., 1999; Kwak et al., 2000; Ozaki et al., 2000; Saishin et al., 2003), but they fail to cause regression of new vessels (K. Takahashi and P. A. Campochiaro, unpublished data). This is supported by observations in patients with choroidal neovascularization treated with VEGF antagonists in whom leakage is reduced, but the choroidal neovascularization is not eliminated (Gragoudas et al., 2004). Regression of neovascularization is likely to be needed to achieve optimal results. Systemic or intraocular administration of VEGF-rGel to achieve regression of neovascularization combined with a VEGF antagonist to prevent recurrence is an appealing strategy that deserves investigation.

Fig. 6. Intravitreal injection of VEGF/rGel causes regression of ischemia-induced retinal neovascularization. Mice were placed in 75% oxygen at P7 and at P12, they were removed to room air. At P17, the baseline amount of neovascularization was measured (n = 6), and the remaining mice (n = 7) were given an intravitreal injection of 5 ng of VEGF/rGel in one eye and 5 ng of rGel in the other eye. At P21, ocular sections stained with G. Simplex/lectin E4 showed prominent baseline neovascularization on the surface of the retina in P17 mice (A and B, arrows). Substantial neovascularization was also seen at P21 in eyes that had been injected with rGel (C and D, arrows), but almost no neovascularization was detectable in eyes that had been injected with VEGF/rGel (E and F, arrows). Measurement of the area of retinal neovascularization by image analysis showed that at P21 eyes injected with VEGF/rGel had less neovascularization than that seen in eyes injected with rGel and less than the baseline neovascularization at P17 (G). *p < 0.0001 for difference from baseline by linear mixed model. †, p < 0.0001 for difference from gelonin by linear mixed model. Scale bar, 100 µm.
