Received January 11, 2007; accepted March 28, 2007

ABSTRACT

A major challenge to broadening oncology applications for inhibitors of the ubiquitin-proteasome system (UPS) is the identification of UPS-dependent cancer pathways predictive of tumors responsive to peptidomimetic inhibitors of its 20S core protease activity. To inform clinical studies evaluating UPS inhibitors as breast cancer therapeutics, seven phenotypically diverse human breast cancer cell line models were characterized for their cellular and molecular responses to the clinically approved 20S inhibitor bortezomib (PS341; Velcade), focusing on those overexpressing estrogen receptor (ER) or ERBB2/HER2, because these oncogenic receptor pathways are constitutively activated in ~80% of all breast cancers. All models demonstrated dose-dependent bortezomib reduction in intracellular 20S activity correlating with cell growth inhibition, and bortezomib IC50 values (concentrations producing 50% growth inhibition) varied directly with pretreatment 20S activities (r = 0.74; * p < 0.05), suggesting that basal 20S activity may serve as a clinical predictor of tumor responsiveness to UPS inhibition. Reduction in 20S activity (> 60%) was associated with early (24 h) intracellular relocalization of ER (nucleus to cytoplasm) and ERBB2 (plasma membrane to perinuclear lysosomes), buildup of ubiquitinated and Hsp70-associated receptors, degradation and loss of ER and ERBB2 function, and induction of cellular apoptosis. These models were also used to screen a pharmacologic panel of pathway-targeted anti-cancer agents [4-hydroxy-3-methoxy-5-((benzothiazol-2-yl)imino)benzylideneacyanocetamide (AG825), 6-(4-bromo-2-chloro-phenylamino)-7-fluoro-3-methyl-3H-benzoimidazole-5-carboxylic acid (2-hydroxy-ethoxy)-amide (AZD6244/ARY142886), 2-(4-morpholinyl)-8-phenyl-4H-1-benzoypyran-4-one hydrochloride (LY294002), 17-N-allylaminomethyl-17-demethoxy geldanamycin (17AAG), and (2E)-N-(4-hydroxy-3-[[2-(2-hydroxyethyl)]ethyl]amino[methyl]phenyl]-2-propenamide (LAQ824)] for those capable of sensitizing to bortezomib. In keeping with the observation that 20S reduction has little effect on mitogen-activated protein kinase kinase 1/2 (MEK1/2) signaling in either ER-positive or ERBB2-positive models, only the MEK-1/2 inhibitor AZD6244 consistently improved the antitumor activity of bortezomib.

The 26S (2-MDa) multicatalytic ubiquitin-proteasome system (UPS) is responsible for the degradation of all short-lived and the majority of long-lived proteins in mammalian cells. The 20S axial pore complex possesses regulated protease activities, whereas the 19S multicaper component regulators the energy-dependent binding, unfolding, and entry of ubiquitin-tagged substrates into the 20S core, thereby directly controlling transcription, cell cycle progression, and survival, as well as the elimination of misfolded and aggregated proteins formed in the cytosol, endoplasmic reticulum, or nucleus (Voorhees and Orlowski, 2006). Despite this central role in all normal cell biology, the UPS has become a validated cancer therapeutic target after the clinical development of peptidomimetic small-molecule inhibitors of 20S core proteases and the 2003 FDA approval of the dipeptide ABBREVIATIONS: ER, estrogen receptor; MEK, mitogen-activated protein kinase kinase; ERK, extracellular signal-regulated kinase; AG825, 4-hydroxy-3-methoxy-5-((benzothiazol-2-yl)imino)benzylideneacyanocetamide; PI3K, phosphatidylinositols 3-kinase; LY294002, 2-(4-morpholinyl)-8-phenyl-4H-1-benzopyran-4-one hydrochloride; AZD6244, 6-(4-bromo-2-chloro-phenylamino)-7-fluoro-3-methyl-3H-benzoimidazole-5-carboxylic acid (2-hydroxy-ethoxy)-amide; LAQ824, (2E)-N-(4-hydroxy-3-[[2-(2-hydroxyethyl)]ethyl]amino[methyl]phenyl]-2-propenamide; MCP5, 3-(N-morpholinol)propanesulfonic acid; NP-40, Nonidet P-40; DAPI, 4,6-diamidino-2-phenylindole; NF-xB, nuclear factor xB; Hsp90, 90-kDa heat shock protein; Hsp70, 70-kDa heat shock protein; 17-AAG, 17-N-allylaminomethyl-17-demethoxy geldanamycin; NPI-0052, salinosporamide A; HDAC, histone deacylase; UPS, ubiquitin-proteasome system.
boronate, bortezomib (PS341; Velcade) for the treatment of refractory multiple myeloma (Kissel and Goldberg, 2001; Voorhees and Orlowski, 2006). Not only are cancer cells apparently more dependent than normal cells on 26S-mediated degradation of growth and survival receptors, signaling intermediates, and transcription factors but also it has recently been shown in human breast cancer cell lines that growth factors also up-regulate transcript and protein levels for the key ATPase subunit within the 19S complex that controls entry into the 20S core (Barnes et al., 2005).

Whereas bortezomib selectively and reversibly inhibits the 20S chymotryptic site in UPS, newer and potentially more potent antitumor proteasome inhibitors capable of irreversibly inhibiting the 20S chymotryptic, tryptic, and caspase sites have now entered clinical trials (Joazeiro et al., 2006). The antitumor activity of all proteasome inhibitors seems to be associated with induction of cell cycle arrest and apoptosis, commonly attributed to inhibition of NFκB (Wang et al., 1999; Feinman et al., 2004). However, different proteasome inhibitors can activate distinct proapoptotic pathways (Chauhan et al., 2005; Cusack et al., 2006), and a major challenge for broadening the clinical application of these novel agents is identifying which among the many pathways downstream of proteasome inhibition are most essential for and predictive of their anticancer activity (Joazeiro et al., 2006). Although bortezomib and newer proteasome inhibitors are being clinically evaluated partly because of their ability to sensitize or overcome resistance to standard chemotherapeutics, the choice of drugs for clinical combination with these inhibitors remains largely empirical (Joazeiro et al., 2006; Voorhees and Orlowski, 2006). For the treatment of breast cancer in particular, bortezomib failed to show significant single-agent activity in initial clinical trials, leading to the recommendation that future clinical efforts target the UPS in specific subsets of breast cancer guided by more informative preclinical evidence (Dees and Orlowski 2006; Cardoso et al., 2004; Yang et al., 2006).

Recognizing the broad diversity of naturally occurring human breast cancers, we evaluated a clinically representative panel of seven phenotypically diverse human breast cancer cell line models and characterized their cellular and molecular responses to bortezomib, focusing on estrogen receptor (ER, α isoform) and ERBB2/HER2 receptor pathways, because either of these pathways is constitutively activated in ~80% of all breast cancers. All cell lines in the panel demonstrated dose-dependent bortezomib reductions in intracellular 20S activity; and bortezomib IC_{So} (50% growth inhibition concentration) values were found to correlate with pretreatment (basal) 20S proteasome activity. Downstream proteasome targets inhibited within 24 h of exposure to an IC_{So} bortezomib dose included ER and ERBB2 mechanisms in cell lines whose growth and survival are dependent on these receptor pathways. We were surprised to find that bortezomib seemed relatively inefficient at inhibiting MEK1/2 generation of phospho-ERK1/2(44/42) in both ER-positive and ERBB2-positive breast cancer models. To guide future clinical studies, a pharmacologic panel of diverse pathways inhibitors was tested against the ER-positive and ERBB2-positive breast cancer models to identify targeted therapeutics able to enhance the anticancer activity of bortezomib. In keeping with the observation that 20S reduction produced little effect on MEK1/2 signaling in these models, a specific MEK1/2 inhibitor (AZD6244/ARRY142886) proved most capable of increasing the antitumor activity of bortezomib.

Materials and Methods

Cell Lines, Reagents, and Cell Viability Assay. The human breast cancer cell lines MCF7, SKBr3, BT474, MDA-433, T47D, and MDA-231 were originally obtained from American Type Culture Collection (Manassas, VA) and were grown under American Type Culture Collection-recommended conditions: 37°C, 5% CO2, and in Dulbecco's modified Eagle's, McCoys 5A, or RPMI-1640 media, supplemented with 10% fetal bovine serum, 1% penicillin-streptomycin, and 10 μg/ml insulin. The MCF7/HER2 subline, overexpressing a constitutively hyperactive ERBB2 receptor kinase and possessing an altered endocrine phenotype, was developed as described previously (Benz et al., 1992). All media and supplements were purchased from Mediatech Inc. (Herndon, VA). Bortezomib was kindly provided by Millennium Pharmaceuticals (Cambridge, MA) and dissolved in dimethyl sulfoxide in a 10 μM stock stored in aliquots at −20°C. Sulforhodamine B reagent was purchased from Sigma-Aldrich (St. Louis, MO). The chemical inhibitor of ERBB2 kinase AG825, the PI3K inhibitor LY294002, and the Hsp90 inhibitor 17-N-allylamino-17-demethoxy geldanamycin (17AAG) were purchased from Calbiochem (San Diego, CA). AZD6244 was a kind gift of AstraZeneca (UK), and LAQ824 was a kind gift from Novartis Pharmaceuticals, Inc. (East Hanover, NJ). Treated and control cells were assayed for cell viability after plating in 12-well culture dishes at 20,000 cells per well and overnight attachment. Drug dissolved in media was added at the indicated concentrations and incubated at 37°C for 2 to 5 days; at the time of assay, 250 μl of ice-cold 50% trichloroacetic acid was added to each well and incubated at 4°C for 1 h. Plates were washed five times with dH2O before the addition of 500 μl of sulforhodamine B (SRB, 0.4% in 1% acetic acid) and 30-min incubation at room temperature. Plates were rinsed five times in 1% acetic acid; the colored product was solubilized in unbuffered Tris base (pH 10.5) and quantified by absorbance at 564 nm. The optical density reading of four replicates for each treatment was normalized for the mean value of untreated cells and expressed as percentage of control.

Human Breast Cancer Xenograft Model. Trastuzumab-resistant, ERBB2-positive B585 human breast cancer xenografts were grown in nude mice as described previously (Marx et al., 2006). Xenografts were serially passaged as subcutaneous tumors in the flanks of 4- to 6-week-old female nu/nu mice (Taconic Farms, Germantown, NY). B585-bearing mice were given intraperitoneal injections of vehicle or bortezomib (1 mg/kg) on days 15, 19, 22, 26, and 29; animal weights and three-dimensional tumor measurements were determined at least twice weekly, and time-dependent mean (± S.D.) tumor volumes were calculated and plotted. Additional B585-bearing mice were given a single i.p. injection of vehicle or 1 mg/kg PS-341 when B585 growth rates had achieved at least 300 mm^3/day; these mice were sacrificed 24 h after treatment to measure single-dose drug effects on resected and snap-frozen (−80°C) B585 tumors. Frozen samples were pulverized into a fine powder under liquid nitrogen for further assay. For protein analysis, tumor powders (0.02 g per sample) were homogenized by sonication (550 Sonic Dismembrator; Fisher Scientific, Pittsburgh, PA) twice for 15 s each in 100 μl of ice-cold extraction buffer (50 mM HEPES, pH 7.5, 100 mM NaCl, 2 mM Na_2VO_3, 1% NP-40, 0.01% SDS, and 1% deoxycholate) with/without a protease inhibitor cocktail (Mini Complete; Roche Diagnostics, Mannheim, Germany).

20S Proteasome Activity Assay. Harvested cells or pulverized tumor tissues were lysed in buffer consisting of 50 mM HEPES, pH 7.5, 100 mM NaCl, 2 mM Na_2VO_3, 1% NP-40, 0.01% SDS, and 1% deoxycholate. Extracts were incubated on ice for 30 min and clarified by centrifugation for 15 min at 4°C. Protein concentration in the supernatant was determined using the Bradford assay (Bio-Rad...
Laboratories, Hercules, CA). Approximately 50 µg of total cell lysate was added to 0.5 mL Leu-Leu-Val-Tyr-amino-4-methylcoumarin (Chemicon, Temecula, CA) substrate and volumes were equalized in assay buffer (25 mM HEPES, pH 7.5, 5 mM EDTA, 0.5% NP-40, and 0.01% SDS). Assay mixture was prepared in a 96-well fluorometer plate and incubated for 2 h at 37°C. At the end of the incubation period, fluorescence was read using a 390/460 nm filter set in a fluorometer. A fluorescence standard curve with known dilutions of substrate was generated in parallel with the assay samples and results were expressed in arbitrary fluorescence units per micromgram of protein in the assay sample.

Immunoprecipitation and Immunoblot Assays. For immunoblotting, harvested cells or pulsed tumor tissues were lysed in modified RIPA buffer (50 mM HEPES, pH 7.5, 100 mM NaCl, 2 mM Na3VO4, 1% NP-40, 0.01% SDS, and 1% deoxycholate) containing a protease inhibitor cocktail (Mini Complete) and homogenized by sonication (550 Sonic Dismembrator) twice for 10 s each. Extracts were incubated on ice for 20 min and then clarified by centrifugation for 10 min at 4°C. Protein content of supernatants was determined by Bradford assay (Bio-Rad Laboratories). Lysate protein (25–30 µg) was heated to 95°C in 2/1000 sample buffer (100 mM Tris, pH 6.8, 4% SDS, 20% glycerol, and 5% 2-mercaptoethanol) and electrophoresed in 4 to 12% Nu-Page Bis-Tris gradient gels (Invitrogen, Carlsbad, CA). Gels were stained with 0.25% Coomassie blue R-250, destained with 6% methanol and 7% acetic acid, and dried. Membranes were then incubated with the antibodies listed below, stripping with Restore Western Blot stripping buffer before gel electrophoresis and immunoblotting as described above. For lysosomal protease inhibitor experiments, SKBr3 cells were treated as above and extracted in NP-40 buffer containing 50 mM Tris-HCl, pH 7.5, 150 mM NaCl, 1% NP-40, 10 mM NaF, 1 mM sodium vanadate, and a protease inhibitor cocktail (Mini Complete) and homogenized by sonication. Protein aliquots of 750 µg were preclaried with protein A-Sepharose beads and then incubated with 5 µg of mouse monoclonal anti ERBB2 antibody (Calbiochem) for 1 h at 4°C under continuous agitation. Immune complexes were recovered by adding 50 µl of Protein A Sepharose beads (Santa Cruz Biotechnology), washing three times in lysis buffer without NP-40 and resuspending in 50 µl of 2× Laemmli sample buffer before gel electrophoresis and immunoblotting as described above. For lysosomal protease inhibitor experiments, SKBr3 cells were pretreated with 100 µM chloroquine for 1 h before incubation with 10 nM bortezomib for 48 h. A second dose of chloroquine was added 24 h after the first dose. Cell lysates were prepared and analyzed by gel electrophoresis and immunoblotting as described above.

Immunofluorescence Imaging. Cells were seeded in eight-chamber slides (Lab-Tek II; Nalge Nunc International, Rochester, NY) until confluent and then treated with bortezomib as described below. For SKBr3 and BT474 immunofluorescence experiments, cells were treated with bortezomib at 25 nM for 24 and 48 h before fixing in PFA. For experiments with MCF7 cells and detection of the estrogen receptor, cells were serum-starved for 24 or 48 h before treatment. Cells were then treated with 25 nM bortezomib for 24 h and stimulated with 10 nM estradiol for 20 min before fixing. Cells were then washed with PBS and fixed with 4% PFA for 10 min at room temperature. After permeabilization in 0.5% Triton X for 10 min, cells were blocked in 5% serum of secondary antibody host diluted in TBS for 30 min at room temperature and incubated in primary antibody diluted in 2.5% serum overnight. Primary antibodies used were mouse monoclonal anti-ERBB2/HER2 (Calbiochem) and anti-ER alpha (Santa Cruz Biotechnology). Secondary antibodies were donkey-anti mouse Alexa Fluor 488 and donkey anti-rabbit Alexa Fluor 555 (both from Invitrogen), diluted in 2.5% donkey serum and incubated for 30 min. Slides were mounted in Prolong Gold (Invitrogen) with DAPI and left overnight before fluorescent microscopic visualization and imaging.

NFkB DNA-Binding Assays. Quantitative p50 and p65 NFkB DNA-binding was determined using an enzyme-linked immunosorbent assay-based Trans-AM assay in accordance with the manufacturer’s instructions (Active Motif, Carlsbad, CA). In this commercial kit, a duplexed NFkB oligonucleotide, containing the B-cell κ-enhancer consensus binding sequence (5′-AGT TGA GGC GAC TTT CCC AGG C-3′) is attached to the surface of 96-well plates. Activated NFkB in tumor extracts that is first bound to the attached oligonucleotide is specifically and quantitatively detected by subsequent incubation with p50 or p65 specific antibody followed by an enzyme (horse-radish peroxidase)-linked secondary for colorimetric (OD450 absorbance) scoring.

Estrogen Responsive Transcriptional Reporter Assay. Cultures were seeded 1 day before transfection with luciferase (luc) reporters to a density of 1 to 2 × 104 cells per well in 96-well microtiter plates and using appropriate growth media. Cells were transiently transfected with 0.5 µg of ERERE9-luc reporter plasmid (Promega) along with FuGene 6 transfection reagent (Roche). The Renilla reniformis luciferase vector pRL-TK-luc (Promega) was co-transfected to normalize for transfection efficiency. Culture media was changed 20 h after transfection, and cells were then treated with bortezomib (25 nM) for 24 h. Cells were subsequently washed with PBS, lysed for Dual-Glo luciferase assay (Promega), and reporter activity was measured by luminometer. Transfections were reported as -fold change in luciferase activity over vehicle-treated control cells.

Results

Bortezomib Reduction in Breast Cancer Growth (IC50 Values) and 20S Activity Correlated with Pretreatment (Basal) 20S Proteasome Activity. Exposure (72 h) of the human breast cancer cell line panel to increasing concentrations of bortezomib resulted in dose- (Fig. 1A) and time-dependent (Fig. 1B) inhibition of cell growth, as assessed by sulforhodamine B viability, and revealed different sensitivities to this proteasome inhibitor. ERBB2-positive SKBr3 cells showed the greatest sensitivity and lowest bortezomib IC50 (4 nM for 72-h exposure); in contrast, ERBB2-negative MCF7 cells showed significantly reduced sensitivity within 24 h of bortezomib treatment generally correlated to IC50 bortezomib doses invariably reduced intracellular proteasome activity to <40% of basal levels within 6 h. Although there was no apparent correlation between bortezomib sensitivity and breast cancer clinical phenotype (ERBB2 and ER status), the pretreatment (basal) level of 20S proteasome activity in these cells correlated (r = 0.74; *p <
0.05) with bortezomib IC$_{50}$ value (Fig. 1D), indicating that breast cancer cells with lowest basal 20S proteasome activity are most sensitive to growth inhibition by bortezomib.

**Proteasome Inhibition Caused Destabilization and Lysosomal Decay of ERBB2 with Reduction in Phospho-AKT and Induction of Apoptosis.** Despite their differential sensitivity to bortezomib, the ERBB2-positive SKBr3 and BT474 cells showed similar intracellular responses to growth-arresting and apoptosis-inducing doses of bortezomib, suggesting that the ERBB2-dependent growth and survival mechanisms in these two cell lines are similarly dependent on the UPS. After 48-h treatment of the more sensitive SKBr3 cells with 5 nM bortezomib, apoptosis was induced as indicated by an increase in the caspase-3 mediated PARP1 cleavage product, p85 PARP; this was associated with loss of phospho(Y1248)-ERBB2 and reduced phospho-AKT (Fig. 2A) levels. For the less sensitive BT474 cells, this same response required a 25 nM dose of bortezomib. We were surprised to find that phospho-ERK1/2 levels were not significantly altered in either cell line, indicating that an ERBB2 receptor-inhibiting and apoptosis-inducing dose of bortezomib does not impair activity of the mitogen activated protein kinase kinases, MEK1/2.

Because the Hsp90 chaperone protein is known to stabilize the active conformation of receptors such as ERBB2 and their downstream signaling effectors such as AKT (Xu et al., 2001; Calderwood et al., 2006), the early effect of bortezomib treatment on ERBB2 chaperone binding was evaluated by immunoprecipitation and immunoblotting. Within a 24-h bortezomib treatment (10 nM) of either SKBr3 or BT474 cells, the association of Hsp90 with endogenous ERBB2 receptor was lost and replaced by another coprecipitating chaperone protein, Hsp70 (Fig. 2B). This altered chaperone binding occurred before significant loss in receptor content (Fig. 2A) but in conjunction with a buildup in ubiquitinated ERBB2 protein, detected in the same immunoprecipitates (data not shown).

At 24 h after bortezomib treatment of SKBr3 cells, immunofluorescent microscopic imaging was used to monitor the intracellular localization of the destabilized ERBB2 receptors. Although vehicle-treated cells showed only plasma membrane-localized ERBB2 receptor, chaperone-altering doses of bortezomib induced complete relocalization of ERBB2 within 24 to 48 h into a perinuclear cytoplasmic compartment (Fig. 2C) that colocalized with both immunoreactive lysosomal protein, LAMP1, and the endoplasmic reticulum marker, calreticulin (results not shown). A similar result was obtained with BT474 cells after 48 h of bortezomib treatment.
treatment (results not shown). Cotreatment of SKBr3 cells with a nontoxic dose of the lysosomal processing inhibitor chloroquine prevented bortezomib-induced ERBB2 decay in these cells (Fig. 2D).

**Phospho-AKT Reduction Was Associated with In Vivo Inhibition of 20S Proteasome Activity and Reduced ERBB2-Positive Breast Cancer Growth.** The trastuzumab-resistant, ERBB2-positive B585 human breast cancer xenograft model was used to determine the relative sensitivity of intratumor NFκB DNA-binding, phospho-ERK1/2 and phospho-AKT levels in response to bortezomib treatment sufficient to reduce 20S proteasome activity and B585 growth in vivo. With maximally tolerated dosing of bortezomib (twice weekly 1 mg/kg i.p. injections ×4 into tumor-bearing nude mice) nude mouse tumor volumes showed a modest growth inhibiting treatment effect, with mean tumor volumes determined after the second, third, and fourth injections (days 22, 26, and 29) reduced no more than 30% relative to vehicle-treated control mice (Fig. 3A). A parallel set of mice bearing palpable tumors growing at >300 mm³/day were treated with a single i.p. injection of either vehicle or bortezomib (1 mg/kg), and their tumors were resected 24 h later to assess intratumor 20S proteasome activity, NFκB (p50 and p65) DNA-binding, phospho-ERK1/2, and phospho-AKT levels. Tumors treated with a single injection of the growth-inhibiting bortezomib dose showed a mean 40% reduction in intratumor 20S proteasome activity relative to the vehicle-treated tumors (Fig. 3B). At this level of proteasome inhibition, tumor NFκB p50 and p65 DNA-binding activities were unaffected, as were tumor phospho-ERK1/2 levels (Fig. 3, C and D). In contrast, tumor phospho-AKT levels were reduced to 50% of control tumor levels (Fig. 3D).

**Proteasome Inhibition Causes ER Relocalization and Decay with Loss of Transcriptional Function and Induction of Apoptosis.** Treatment of ER-positive MCF7 cells with growth inhibitory doses of bortezomib caused a marked dose-dependent reduction in ER content by 48 h (Fig. 4A); this was accompanied by loss of the proliferation marker cyclin D1, increase in the apoptosis marker p85 PARP, and a prominent increase in the proapoptotic and mitotic checkpoint protein p53. However, significant changes in phospho-AKT or phospho-ERK1/2 levels were not detected (data not shown). To assess early effects of proteasome inhibition on ER function, MCF7 cells were transiently transfected with a luciferase reporter driven by an ERE-regulated promoter (ERE₅-TK-Luc); and as control for transfection efficiency and overall cell viability, a parallel set of MCF7 cells were transfected with an *R. reniformis* luciferase vector (TK-Luc). After transient transfection (20 h), MCF7 treated with bortezomib (25 nM) for 24 h showed a 40% specific reduction in ER transcriptional activity (ERE₅-TK-Luc activity), relative to vehicle-treated cells or bortezomib-treated MCF7 transfected with the TK-Luc vector (Fig. 4B). This early loss of ER transcriptional activity preceding bortezomib-induced loss of ER content suggested the possibility of a functional impairment in ER localization, as reported for other hormone receptors after proteasome inhibition (Shenoy et al., 2001; Yu and Malek, 2001; Lin et al., 2002). Immunofluorescence imaging

![Fig. 2](http://molpharm.aspetjournals.org)
for ER localization was performed on MCF7 cells treated with vehicle or bortezomib (25 nM, 24 h). Whereas ER colocalized with DAPI nuclear staining in control cells, all bortezomib-treated cells showed cytoplasmic localization of ER (Fig. 4C), indicating that bortezomib altered ER trafficking by inhibiting either cytoplasm-to-nucleus translocation or inducing nucleus-to-cytoplasm retrotranslocation of ER.

**Pharmacologic Targeting of Pathways in Combination with Proteasome Inhibition.** To identify breast cancer targets that might complement proteasome inhibition, the panel of cell lines was treated for 48 h with IC_{50} bortezomib doses in combination with the following target inhibiting drugs and doses: histone deacetylases (LAQ824, 10 nM), Hsp90 (17AAG, 50 nM), ERBB2 kinase (AG825, 25 \mu M), PI3K (LY294002, 10 \mu M), or MEK1/2 (AZD6244, 100 nM). The resulting growth inhibitory interactions were scored as antagonistic, additive, or supra-additive; however, no supra-additive bortezomib combinations were identified. Against ER-positive breast cancer cells (MCF7, BT474), only bortezomib combinations with LAQ824 or AZD6244 were additive. Against ERBB2-positive breast cancer lines (BT474, SKBr3), only bortezomib combinations with AG825 or AZD6244 were consistently additive. Against ER-negative cell lines (MDA231, SKBr3), only bortezomib in combination with AZD6244 was consistently additive. These drug interactions are summarized in Table 1; the cell viability and growth effects of these representative drug-bortezomib interactions are demonstrated in Fig. 5. It is noteworthy that near-additive interactions were observed in every cell line when the MEK1/2 inhibitor AZD6244 (100 nM) was used in combination with an IC_{50} bortezomib dose.

**Discussion**

Codony-Servat et al. (2006) studied a panel of human breast cancer cell lines and measured a variety of cellular and molecular consequences after bortezomib treatment but were unable to identify any mechanism-based predictors of bortezomib responsiveness or pathway inhibitors capable of enhancing bortezomib sensitivity. To explore downstream markers of proteasome inhibition and pathways potentially targeted in combination with proteasome inhibitors, we studied a panel of seven human breast cancer cell line models representing clinically diverse phenotypes and expressing a wide range of endogenous 20S proteasome activities. All models demonstrated dose-dependent bortezomib reduction in intracellular 20S activity correlating with cell growth inhibition; bortezomib IC_{50} values varied directly with pre-
treatment 20S activities \((r = 0.74, *, p < 0.05)\), suggesting that basal 20S activity may serve as a clinical predictor of tumor responsiveness to UPS inhibition.

These breast cancer models also indicated that 6- to 24-h exposure to an IC\(_{50}\) bortezomib dose invariably reduced intracellular 20S activity by >60% from pretreatment levels. In contrast, the B585 xenograft study showed that maximally tolerated dosing of bortezomib produced only a 40% reduction in B585 20S proteasome activity. Although this was associated with modest in vivo inhibition of B585 growth, the 40% reduction in B585 20S activity suggests that in vivo bortezomib bioavailability may be limiting for some solid tumors.

**Fig. 4.** Early in vitro effects of proteasome inhibition on ER receptor content, intracellular localization and transcriptional activity, cell proliferation, and survival signals. A, ER overexpressing MCF7 breast cancer cells were treated with the indicated growth-suppressing concentrations of bortezomib (PS341) before extraction and immunoblotting to measure levels of total ER (α isoform), cyclin D1, p53, actin, and the caspase-cleaved apoptotic product, p85 PARP. B, after transient transfection of MCF7 cells with either ERE\(_3\)-TK-Luc (luciferase) or TK-Luc (\(R.\ reniformis\) luciferase) reporters, cell cultures were treated with vehicle or bortezomib (25 nM x 24 h), and then lysates were analyzed and mean (±S.D.) fold-changes in luciferase activity over vehicle-treated control reporter activity recorded. C, intracellular ER (green) was localized by immunofluorescence microscopy 24 h after vehicle or bortezomib (25 nM) treatment of MCF7 cells (left), as described under Materials and Methods. DAPI (blue) was used to counterstain MCF7 cell nuclei in the same field (middle). Merging of green-stained ER and blue-stained nuclear images demonstrates overlapping nuclear origin of ER signals in control MCF7, but distinct perinuclear origin of ER signals in treated cells (right).

**TABLE 1**

Summary of antagonistic (\(\text{-}\)) or additive (\(\text{+}\)) cell growth effects of targeted agents tested in combination with bortezomib (IC\(_{50}\) dose) against the indicated breast cancer cell line models.

insufficient to affect all the cancer pathways affected by an in vitro IC\textsubscript{50} dose of bortezomib. However, these B585 xenograft studies confirmed that for ERBB2-positive breast cancers, reduction in phospho-AKT is a more sensitive indicator of 20S inhibition than either NF\textkappa B or MEK1/2 activity. With the clinical introduction of newer and more broadly acting proteasome inhibitors such as NPI-0052 (Cusack et al., 2006; Joazeiro et al., 2006), it is reasonable to expect improved solid tumor bioavailability and greater inhibition of 20S proteasome activity, with resulting impairment of ERBB2 and ER breast cancer pathways at least comparable with those observed by in vitro treatment of our cell line models with IC\textsubscript{50} bortezomib doses.

With >60% reduction in 20S proteasome activity, bortezomib inhibited cell growth by inducing cellular apoptosis (measured by increases in the caspase-3 mediated PARP1 cleavage product, p85), mediated in ER-positive and ERBB2-positive breast cancer models by different proteasome-dependent mechanisms. In the ER-positive MCF7 cell line model, down-regulation of ER content and transcriptional activity by bortezomib were associated with up-regulation of the tumor suppressing protein, p53 (wild type), which undoubtedly contributed to the inhibition of cyclin D1 levels and cell cycle progression as well as induction of apoptosis detected by the caspase-3 mediated PARP1 cleavage product, p85. Within 24 h of MCF7 treatment, bortezomib induced a cytosolic buildup of ubiquitinated and Hsp70-associated undegraded ER (data not shown); these findings have been described previously and attributed to the critical function of the proteasome in maintaining nuclear receptor turnover and transcriptional activity (Lonard et al., 2000, Reid et al., 2003). Not previously reported is the observed bortezomib induced early relocalization of ER from nuclear to cytoplasmic compartments. Lin et al. (2002) found a similar response for androgen receptor (AR) after cellular treatment with the proteasome inhibitor MG132; in that study, proteasome inhibition for >24 h suppressed AR nuclear translocation by 50%, disrupted AR interactions with its coregulators, and reduced total AR content of prostate cancer cells. Further studies are needed to understand the proteasome-dependent mechanisms regulating nuclear receptor trafficking.

Unlike the cell growth and survival mechanisms activated...
by overexpressed ER in MCF7 cells, the constitutive overexpression of ERBB2 receptor tyrosine kinase activity drives growth and survival of SKBR3 and BT474 breast cancer cells primarily by heterodimerization with and phosphorylation of the ERBB3 receptor, which serves to activate the downstream PI3K/AKT pathway. Within 48 h of a 20S reducing dose of bortezomib, surface membrane localized ERBB2 was lost in association with reduced phospho-AKT levels and the induction of cellular apoptosis in SKBr3 and BT474 cells but without any detectable change in MEK1/2 activity as measured by phospho-ERK1/2 levels. The novel finding that 20S proteasome inhibition causes dissociation of the Hsp90 chaperone protein from ERBB2 receptor is similar to the reported ERBB2 effect induced by an Hsp90-inhibiting dose of bez-quinone ansamycins such as geldanamycin or its clinical analog 17AAG (Xu et al., 2001). Treatment of ERBB2-positive cells with bortezomib, as with ansamycins, seems to shift ERBB2 chaperone association from one that is stabilizing (Hsp90) to one that is destabilizing (Hsp70). In ansamycin-treated cells, dissociation of ERBB2 from Hsp90 is followed by proteasomal degradation of ERBB2; however, in cells treated with the proteasome inhibitor bortezomib, the loss of ERBB2 content must occur by a different mechanism. One contributing possibility is the recently described repression of ERBB2 transcript levels caused by various proteasome inhibitors (Marx et al., 2006). A more likely explanation for the rapid loss of total ERBB2 content is that after proteasome inhibition, the destabilized and ubiquitin-tagged ERBB2 is sequestered within perinuclear aggresomes, where it is degraded by lysosomal proteases, consistent with the observed prevention of ERBB2 degradation by the lysosome inhibitor chloroquine. Microtubule-mediated transport and accumulation of polyubiquitinated proteins into aggresomes has recently been reported (Johnston et al., 1998; Nawrocki et al., 2006). However, further study of proteasome-dependent ERBB2 trafficking mechanisms is needed, because the observed perinuclear sequestration of ERBB2 could also have resulted from bortezomib-induced disruption of normal ERBB2 endocytic mechanisms (Austin et al., 2004).

Approximately 80% of human breast cancers overexpress ER and/or ERBB2 receptors. Despite available therapeutics that specifically target these overexpressed receptors, clinical resistance to these target-specific agents is common. Therefore, there is both clinical need and interest in applying proteasome inhibitors to improve the treatment of breast cancer (Cardoso et al., 2004; Dees and Orlowski, 2006). However, because of the diversity of breast cancer phenotypes, it is also appreciated that rational combination of proteasome inhibitors with other targeted therapeutics must be guided by informative preclinical studies (Yang et al., 2006). Based on the above observations that 20S proteasome inhibition can be cytotoxic to ER- and ERBB2-overexpressing breast cancer cells by different mechanisms, our cell line models were used to screen a pharmacologic panel of diverse pathway inhibitors to identify targeted agents capable of sensitizing to bortezomib. The five targeted agents shown in Table 1 (AG825, AZD6244, LY294002, 17AAG, LAQ824) were tested at doses previously shown to inhibit their pathways, although when used as single agents, these inhibitors produced quite variable cell line-dependent growth inhibition. The Hsp90 inhibitor 17AAG proved antagonistic in combination with bortezomib against all models tested; this finding is in contrast to the ansamycin result reported by Mimnaugh et al. (2004), although it is consistent with the fact that Hsp90 inhibitors induce proteasomal decay of Hsp90 client proteins (e.g., ER, ERBB2, AKT), which is not possible in the presence of effective 20S inhibition. The ERBB2 kinase inhibitor AG825 and the PI3K inhibitor LY294002 enhanced bortezomib cytotoxicity but only in ERBB2-positive cells in which these target kinases were constitutively activated. The histone deacetylase (HDAC) inhibitor LAQ824 was antagonistic to bortezomib only in the same ERBB2-positive breast cancer cell lines previously shown to be most sensitive to this and other HDAC inhibitors (Scott et al., 2002), suggesting that HDAC and proteasome mechanisms have overlapping and non-complementary growth-regulating roles in ERBB2-positive but not ERBB2-negative malignant cell lines. This possibility deserves further study given the report that the shutting of misfolded proteins into the aggressome, a potential consequence of proteasome inhibition, is HDAC-dependent (Kawaguchi et al., 2003). Unlike the other targeted agents evaluated, only the MEK1/2 inhibitor AZD6244 proved capable of additively enhancing the growth-inhibiting effect of bortezomib in all breast cancer models studied. Because bortezomib was relatively inefficient at inhibiting MEK1/2 in both ER-positive and ERBB2-positive breast cancer cells, and a MEK1/2 inhibiting dose of AZD6244 (100 nM), by itself, failed to significantly inhibit the growth of three of the breast cancer cell lines (SKBr3, BT474, and MCF7), the observed additive interaction between AZD6244 and bortezomib suggests that each agent is acting on independent but complementary growth regulating mechanisms. Thus, compared with the other targeted agents evaluated in these models, AZD6244 would seem to be the most promising agent for further preclinical evaluation in combination with a 20S inhibiting dose of bortezomib or newer generation proteasome inhibitor.

Acknowledgments

We thank Donghui Wang (University of California, San Francisco, CA) for technical assistance with the xenograft studies. Bortezomib was kindly provided by Millennium Pharmaceuticals (Cambridge, MA); AZD6244 was provided by AstraZeneca (London, UK); and LAQ824 was provided by Novartis Pharmaceuticals, Inc. (East Hanover, NJ).
