ABSTRACT

The calcium-sensing receptor (CaR) belongs to the G protein-coupled receptor superfamily, with a characteristic structure consisting of seven transmembrane helices, an intracellular C-terminal and an extracellular N terminal domain. The primary physiological function of the CaR is the maintenance of constant blood Ca\textsuperscript{2+}/H\textsubscript{11001} levels, as a result of its ability to sense very small changes in extracellular Ca\textsuperscript{2+}/H\textsubscript{11001} (Ca\textsuperscript{2+}/H\textsubscript{11001}o). Nevertheless, in addition to being expressed in tissues involved in Ca\textsuperscript{2+}/H\textsubscript{11001} homeostasis, the CaR is also expressed in tissues not involved in mineral homeostasis, suggestive of additional physiological functions. Numerous agonists and modulators of the CaR are now known in addition to Ca\textsuperscript{2+}/H\textsubscript{11001}o, including various divalent and trivalent cations, aromatic L-amino acids, polyamines, and aminoglycoside antibiotics. The signaling of the CaR is also regulated by extracellular pH and ionic strength. The activated CaR couples mainly to the phospholipase Cβ and extracellular signal-regulated kinase 1/2 signaling pathways, and it decreases intracellular cAMP levels, leading to various physiological effects. The recent identification of synthetic allosteric modulators of the CaR has opened up a new field of research possibilities. Calcimimetics and calcilytics, which increase and decrease agonist signaling via the CaR, respectively, may facilitate the manipulation of the CaR and thus aid in further investigations of its precise signaling. These allosteric modulators, as well as strontium, have been demonstrated to have therapeutic potential for the treatment of disorders involving the CaR. This review discusses the various agonists and modulators of the CaR, differences in their binding and signaling, and their roles as therapeutics in various diseases.

The Ca\textsuperscript{2+}-sensing receptor (CaR), initially cloned from the bovine parathyroid, belongs to family 3 (or C) of the G protein-coupled receptor (GPCR) superfamily (Brown et al., 1993). It has a structure characteristic of GPCRs, consisting of seven transmembrane (TM) helices, an intracellular C terminus, and a large extracellular N-terminal domain (ECD), typical of family 3 GPCRs. The ECD is structurally similar to the Venus Flytrap Domain Motif (VFTM) of bacterial periplasmic binding proteins (Brown and MacLeod, 2001; Pin et al., 2003). It has been demonstrated that when expressed at the cell surface, the CaR exists mainly in the form of a dimer (Bai et al., 1998; Zhang et al., 2001), in which the monomers are covalently linked by disulfide bridges involving two cysteine residues (Cys129 and Cys131) within the VFTMs (Ray et al., 1999) (Fig. 1). As is the case for other GPCRs, the activated CaR is capable of activating multiple types of G proteins from different G protein subfamilies, primarily G\textsubscript{q/11} and G\textsubscript{i}. This leads to a range of cellular responses, including stimulation of phospholipase Cβ (PLCβ), production of inositol 1,4,5-triphosphate (IP\textsubscript{3}), release of intracellular Ca\textsuperscript{2+} (Ca\textsuperscript{2+}/H\textsubscript{11001}), and stimulation of mitogen-
activated protein kinases (MAPKs), and an inhibition of adenylate cyclase, causing a decrease in cAMP levels (Brown and MacLeod, 2001; Maiti et al., 2008) (Fig. 1).

The primary physiological role of the CaR is the maintenance of constant blood Ca\(^{2+}\) levels (1.1–1.3 mM) through continuous adjustments of parathyroid hormone (PTH) release from the parathyroid chief cells, which are highly sensitive to the slightest changes in extracellular Ca\(^{2+}\) (Ca\(^{2+}\)o) (Brown et al., 1993; Brown and MacLeod, 2001). When a decrease in Ca\(^{2+}\)o is sensed, PTH secretion increases, through an as-yet poorly defined mechanism that is likely to involve cytoskeletal components F-actin and caveolin-1 (Quinn et al., 2007). The resultant increase in circulating PTH normalizes the Ca\(^{2+}\)o levels by its actions on the kidneys, bones, and, indirectly, intestines (Brown, 1991; Kurokawa, 1994). The opposite effect on PTH secretion is observed when an increase in Ca\(^{2+}\)o is sensed through the CaR, leading to a decrease in PTH release. In contrast to its actions on the PTH, activation of the CaR by Ca\(^{2+}\)o has a stimulatory effect on calcitonin secretion from C cells of the thyroid (Garrett et al., 1994). The opposite effect on PTH secretion is observed when an increase in Ca\(^{2+}\)o is sensed through the CaR, leading to a decrease in PTH release. In contrast to its actions on the PTH, activation of the CaR by Ca\(^{2+}\)o has a stimulatory effect on calcitonin secretion from C cells of the thyroid (Garrett et al., 1995). Thus, through a refined, bidirectional mechanism, the CaR regulates the secretion of PTH and calcitonin, playing a primary role in the maintenance of Ca\(^{2+}\)o homeostasis.

Many questions about the physiological significance of the CaR have been answered through the identification of mutations of the CaR gene that were demonstrated to cause several hereditary disorders of Ca\(^{2+}\)o sensing. Familial hypocalciuric hypercalcemia (FHH) (Pollak et al., 1993) and neonatal severe hyperparathyroidism (NSHPT) (Pollak et al., 1993) arise from loss-of-function mutations of the CaR gene, which right-shift the set-point for Ca\(^{2+}\)o inhibition of PTH secretion and for stimulation of urinary Ca\(^{2+}\) excretion, whereas autosomal dominant hypocalcemia (ADH) and Bartter Syndrome type V (Watanabe et al., 2002) are caused by gain-of-function mutations of the CaR (Pollak et al., 1994; Zhao et al., 1999). Identification that these disorders are caused by CaR mutations definitively confirmed the involvement of this receptor in Ca\(^{2+}\)o homeostasis (Brown, 1997).

The CaR is widely expressed, and apart from maintaining constant blood Ca\(^{2+}\) levels, it has numerous other functions in different tissues. CaR expression has of course been confirmed in cell types involved in Ca\(^{2+}\)o homeostasis, including the parathyroid (Brown et al., 1993), the thyroid (Garrett et al., 1995), kidneys (Riccardi et al., 1995, 1996) and the bone (Kameda et al., 1998; Montaverri et al., 2006; Chang et al., 2008), as well as in tissues not involved in Ca\(^{2+}\)o homeostasis, such as the brain (Ruat et al., 1995), the large intestine (Sheinin et al., 2000), lens epithelial cells (Chatthopadhyay et al., 1997), the pancreas (Squires et al., 2000), the liver (Canaff et al., 2001), antral gastrin cells (G cells) of the stomach (Ray et al., 1997), and cells of the cardiovascular system (Wonneberger et al., 2000; Ziegelstein et al., 2006), influencing numerous physiological processes, including gastrin acid secretion (Dufner et al., 2005), hepatic bile secretion (Canaff et al., 2001), and insulin release from the β cells of the pancreas (Squires et al., 2000) to name a few, as well as pathological processes such as vascular calcification and atherosclerosis (Alam et al., 2009).

**Agnosts and Allosteric Modulators of the CaR**

CaR ligands are normally classified as orthosteric agonists (type I agonists), which are capable of activating the CaR on their own, and allosteric modulators, which bind to allosteric sites on the CaR and require the binding of an orthosteric agonist to the receptor to produce their effects. Clearly, Ca\(^{2+}\)o is the primary orthosteric agonist of the CaR, and it is the only ligand of this receptor with an incontestable physiological role through the CaR. Other orthosteric agonists include divalent and trivalent cations, including Mg\(^{2+}\), Al\(^{3+}\), Sr\(^{2+}\), Mn\(^{2+}\), Ni\(^{2+}\), Gd\(^{3+}\), and Ba\(^{2+}\) (McGehee et al., 1997; Brown, 2007), aminoglycoside antibiotics (AGAs) (McLarson et al., 2002) and polyamines (Cheng et al., 2004), all of which are positively charged. In general, CaR agonists with a high positive charge density tend to have higher potency. An orthosteric antagonist of the CaR has not yet been identified.

Both positive (type II agonists) and negative allosteric modulators of the CaR have been identified. Aromatic l-amino acids have been demonstrated to act as positive allosteric modulators of the CaR (Lee et al., 2007), and they enhance Ca\(^{2+}\)o signaling (Conigrave et al., 2000). Synthetic positive allosteric modulators of the CaR, known as calcimetics, like aromatic l-amino acids, shift the concentration-response curve of Ca\(^{2+}\)o to the left. Negative allosteric modulators of the CaR are known as calcylitics, and they right-shift the concentration-response curve of Ca\(^{2+}\)o. In addition to the various ligands of the CaR, recent studies have demonstrated that extracellular pH (pH\(_{e}\)) and ion strength are also capable of modulating the activity of this receptor (Quinn et al., 1998, 2004).

Modulation of CaR signaling by exogenous ligands is of great therapeutic interest. For example, Sr\(^{2+}\) (in a ranelic acid form) has been demonstrated to be effective for the treatment of osteoporosis (Kendler et al., 2009), and it is currently used for this purpose, although whether its bene-
ficial effects are produced through the CaR remain to be confirmed. The recent discovery of calcimimetics and calcilytics has created a lot of excitement, as their use allows for a more specific regulation of the CaR in numerous diseases associated with decreased and increased CaR signaling, respectively. Calcimimetics have been described to be effective in the treatment of hyperparathyroidism (HPT) (Quarles et al., 2003), and investigations are currently under way to determine the therapeutic potential of calcilytics in the treatment of osteoporosis (Brown, 2007). Therefore, understanding the precise signaling of the various CaR ligands is of great importance, to minimize the potential adverse effects that may arise through mishandling of a receptor involved in the crucial physiological function of Ca$^{2+}$ homeostasis. The therapeutic applications of various CaR ligands are discussed in further detail below.

**Differential Binding Sites of Various CaR Ligands on the CaR**

The identification of activating and inactivating mutations of the CaR involved in disorders of Ca$^{2+}$ sensing has greatly helped in elucidating the role of individual residues of the CaR in ligand binding and subsequent signaling. Early in vitro studies have demonstrated the causative role of the inactivating mutations of the CaR (for example P55L, N178D, R185Q, Y218S, P221S, R227L, R680C, P747fs, and V817I) in FHH and NSHPT, by observing increased EC$_{50}$ values at activating intracellular pathways through the mutant receptors (Bai et al., 1996; Pearce et al., 1996). In contrast, mutations associated with ADH (for example, F128L, T151M, and E191K) lead to reduced EC$_{50}$ for Ca$^{2+}$ (Pearce et al., 1996). It was hypothesized that the modified signaling of mutant receptors was due either to altered affinity of the receptor for its agonists or to a failure or facilitation to couple and/or activate the available, suitable G proteins, as a result of a modified receptor conformation. In addition, modified cell surface trafficking of receptors could also be a contributing factor (D'Souza-Li et al., 2002).

The precise localization of Ca$^{2+}$ binding has been hampered by the unsuccessful attempts to crystallize the CaR. However, recent studies by Huang et al. (2007, 2009), which have used homology modeling using the metabotropic glutamate receptor type 1 (mGluR1) as a model, have greatly helped in this quest and they have reported the existence of five distinct Ca$^{2+}$ binding sites (sites 1–5) located in the VFTM of the CaR, confirming the generally held belief that the VFTM is not the only site for orthosteric binding. As described above, CaR mutations at residues outside of the VFTM lead to reduced Ca$^{2+}$ sensing; therefore, it is possible that other binding sites for Ca$^{2+}$ exist. Ray and Northup (2002) have created a mutant CaR lacking most of the C- and N-terminal domains, and they have demonstrated that Ca$^{2+}$, Mg$^{2+}$, Gd$^{3+}$, spermine, and poly-l-arginine produced intracellular signaling in HEK293 cells, showing that some of the binding sites for these ligands are also located in the seven TM domains (Ray and Northup, 2002).

Calcimimetic and calcilytic binding sites have previously been shown to be located in the TM helices and extracellular loops of the CaR (Petrel et al., 2003; Miedlich et al., 2004; Petrel et al., 2004) (Fig. 2). Miedlich et al. (2004) have shown that mutations of certain residues present in the TM helices (Phe-668, Phe-684, and Glu-837) reduced the effects of both the calcimimetic NPS 2143 and the calcimimetic NPS R-568. Another residue, Arg-680, was involved only in NPS 2143 binding, possibly as a result of structural differences between the two ligands due to the presence of an alkyl bridge hydroxyl group in NPS 2143 (Fig. 3B). Further studies (Petrel et al., 2003, 2004) have identified additional residues involved in calcimimetic and calcimimetic binding located in TM VI and TM VII (Trp-818, Phe-821, and Ile-841). Thus, the binding pockets of calcimetics and calcilytics are partially overlapping but nonidentical (Fig. 2).

**Orthosteric Agonists and Allosteric Modulators of the CaR**

**Mg$^{2+}$ as an Orthosteric Agonist of the CaR**

Other Divalent and Trivalent Cations As Agonists of the CaR. Magnesium (Mg$^{2+}$) has been recognized for years that in contrast to an increase in PTH secretion observed at low Ca$^{2+}$ levels, a paradoxical reduction in PTH secretion occurs in hypomagnesemic patients (Anast et al., 1972; Mennes et al., 1978; Duran et al., 1984). This phenomenon has been confirmed in vitro, and the release of PTH from parathyroid cells was shown to decrease at low Mg$^{2+}$ (Quitterer et al., 2001). Whether the CaR is implicated in this effect was investigated by creating CaR mutants involving residues described to be involved in extracellular Mg$^{2+}$ (Mg$^{2+}$) binding (R185Q, F128L, R795W) (Quitterer et al., 2001). This, however, was without effect, and the Mg$^{2+}$ response remained unaltered using the mutant receptors. In addition to its extracellular functions, Mg$^{2+}$ is known to have a vital intracellular role in modulating the activity of heterotrimeric G proteins by inhibiting guanine nucleotide exchange (Higashijima et al., 1987; Quitterer et al., 2001; La Piana et al., 2008). Thus, modulation of the activity of Gx subunits by Mg$^{2+}$ was proposed as a possible explanation for the paradox; indeed, it was demonstrated that when Gx with reduced affinity for Mg$^{2+}$ was used, CaR activation was no longer affected by Mg$^{2+}$ deficiency (Quitterer et al., 2001). However, despite the paradoxical findings in severely hypomagnesemic patients, under normal situations, the secretion...
of PTH from the parathyroid can also be negatively controlled by Mg$^{2+}$ (Navarro et al., 1999), in a manner similar to Ca$^{2+}$. Furthermore, early studies have shown that patients with FHH, patients with NSHPT, and mice lacking the CaR have elevated serum Mg$^{2+}$ levels, showing that the CaR also acts as a Mg$^{2+}$-sensing receptor in vivo (Ho et al., 1995; Brown, 1997).

Although in general Mg$^{2+}$ produces effects through the CaR similar to those of Ca$^{2+}$, inconsistent sensitivity of the CaR to Mg$^{2+}$ has been reported in different cells and tissues. In the parathyroid, Mg$^{2+}$ has a potency comparable with that of Ca$^{2+}$, whereas sheep parafollicular cells of the thyroid are manyfold less sensitive to Mg$^{2+}$ compared with other divalent cations, with the following rank order: Gd$^{3+}$ > Ba$^{2+}$ > Ca$^{2+}$ > Mg$^{2+}$ (McGehee et al., 1997). The insensitivity of these cells to Mg$^{2+}$ has been suggested to be due to species differences in the CaR (Garrett et al., 1995), possibly because of differential post-translational modifications or expression differences in the CaR (Garrett et al., 1995), similar insensitivity of the CaR to Mg$^{2+}$ was reported by Yamashita and Hagiwara (1990) using the rat calcitonin-secreting cell line rMTC, suggesting that differences exist in CaR signaling by different cations depending on cell type.

Aluminum (Al$^{3+}$). Al$^{3+}$ is present physiologically only in trace amounts in biological systems, and normal serum concentrations of Al$^{3+}$ are less than 0.4 μM (Lajunesse et al., 1998). However, accumulation of Al$^{3+}$ occurs in certain diseases (for example, end-stage renal disease, with Al$^{3+}$ levels at around 5 μM) (Lajunesse et al., 1998). Increased serum Al$^{3+}$ concentrations produce various adverse effects, including central nervous system dysfunction, decreased bone mineral content, and renal failure (Jespersen et al., 1991; Quarles and Dreznier, 1991).

It has been suggested previously that Al$^{3+}$ may produce its physiological effects through the CaR (Lau et al., 1991; Quarles et al., 1997). However, Al$^{3+}$ is a weak agonist of the CaR, and Spurney et al. (1999) have reported that in HEK293 cells transfected with the CaR, Ca$^{2+}$, Mg$^{2+}$, and Gd$^{3+}$ produced an increase in Ca$^{2+}$, levels and IP$_3$ generation in a concentration-dependent manner, but Al$^{3+}$ had no effect at concentrations lower than 1 mM (Spurney et al., 1999).

**Fig. 2.** A schematic representation of the 1078-amino acid human CaR. The predicted orthosteric Ca$^{2+}$-binding site 1 involving the residues Ser-147, Ser-170, Asp-190, Tyr-218, and Glu-297 is shown in purple. Site 2, which consists of residues Asp-215, Leu-242, Ser-244, Asp-248 and Glu-253 is shown in yellow. Site 3, consisting of residues Glu-224, Glu-228, Glu-229, Glu-231, and Glu-232 is demonstrated in pink. Site 4 (Glu-350, Glu-353, Glu-354, Asn-386, Ser-388) and site 5 (Glu-378, Glu-379, Thr-396, Asp-398, Glu-399) are shown in green and blue, respectively (Huang et al., 2009). In three dimensions, the indicated residues form five separate Ca$^{2+}$-binding pockets in the ECD, as predicted with homology modeling using the mGlur1 (Huang et al., 2009). Residues involved in both calcimimetic and calcilytic binding are shown in black (Phe-668, Phe-684, Trp-818, Phe-821, Glu-837, Ile-841). Residues described to play part in calcilytic binding only are shown in orange (Arg-680, Phe-688, Leu-776) (Petrel et al., 2003; Miedlich et al., 2004; Petrel et al., 2004).
These findings were corroborated by Mailland et al. (1997), who also reported a lack of Al\(^{3+}\) activity at micromolar concentrations on IP\(_3\) production in CCL39 fibroblasts transfected with the CaR.

However, using Al\(^{3+}\) concentrations similar to the serum Ca\(^{2+}\) concentrations (0.5–2 mM), a suppression of PTH was observed in an in vitro study using bovine parathyroid cells (Morrissey et al., 1983). This was supported in a study by González-Suárez et al. (2003), in which Al\(^{3+}\) was reported to decrease PTH secretion and cell proliferation in parathyroid glands in nephrectomized Wistar rats with chronic renal failure, treated for 8 weeks with AlCl\(_3\) (González-Suárez et al., 2003). In addition, Al\(^{3+}\) was also demonstrated to inhibit PTH gene expression by a postranscriptional mechanism (González-Suárez et al., 2005). Thus, at millimolar concentrations Al\(^{3+}\) produces effects similar to those of Ca\(^{2+}\). However, the physiological significance of these findings is debatable, because serum Al\(^{3+}\) levels are very low, even in disease states.

Concentrations of Al\(^{3+}\) in the micromolar range have been described to modify various signaling pathways in vitro, including stimulation of PKC and modulation of cAMP production in osteoblasts (Quarles et al., 1994; Hartle et al., 1996). In vivo studies have suggested that at around 50 \(\mu\)M Al\(^{3+}\), de novo bone formation is stimulated, and in vitro studies have shown that osteoblast proliferation increases (Quarles et al., 1988, 1994; Hartle et al., 1996). However, because it has been demonstrated that Al\(^{3+}\) is a weak agonist through the CaR and produces its effect only at concentrations greater than 1 mM (Mailland et al., 1997; Spurney et al., 1999), the reported effects of Al\(^{3+}\) in the micromolar range are likely produced through a different mechanism.

**Strontium (Sr\(^{2+}\)).** Most studies investigating the effects of Sr\(^{2+}\) on the CaR have used a ranelic acid form of the cation.

focusing primarily on its effects in osteoclasts and osteoblasts because of the reported affinity of Sr\(^{2+}\) for bone, where it is taken up into the bone matrix crystals. The specific target of Sr\(^{2+}\) in bone cells has not been clear. Although it has been demonstrated that the effects of Sr\(^{2+}\), such as G protein activation, are maintained in osteoblasts that lack the CaR, suggestive of the involvement of another GPCR in mediating the responses of Sr\(^{2+}\) in bone (Pi and Quarles, 2004), it is now believed that the CaR is one of the mediators of Sr\(^{2+}\)'s effects in bone cells (Fromigue et al., 2009; Hurtel-Lemaire et al., 2009). Sr\(^{2+}\) has been described to stimulate the differentiation of preosteoblasts to osteoblasts through the activation of the CaR, thus increasing bone formation (Bonnelye et al., 2008). It also stimulates the secretion of osteoprotegerin from osteoblasts, leading to an inhibition of the formation of osteoclasts from preosteoclasts, by modulating the osteoprotegerin/Receptor Activator for NF-κB system, which leads to a decrease in bone resorption (Atkins et al., 2009).

Hurtel-Lemaire et al. (2009) have demonstrated that Sr\(^{2+}\) stimulates the apoptosis of primary mature rabbit osteoclasts in a concentration-dependent manner. Both Ca\(^{2+}\)\(_o\) and Sr\(^{2+}\) produced a stimulation of PLC and nuclear translocation of NF-κB in mature osteoclasts through the activation of the CaR. However, the authors have observed a difference between the intracellular effects produced by Ca\(^{2+}\)\(_o\) and Sr\(^{2+}\), showing that Sr\(^{2+}\)-induced osteoclast apoptosis was dependent on PKCβII activation and independent of IP\(_3\) signaling, whereas the effects produced by Ca\(^{2+}\)\(_o\) were independent of the PKCβII pathway and dependent on IP\(_3\). The differential activation of intracellular signaling pathways by

Sr\(^{2+}\) and Ca\(^{2+}\) allows for an additive effect of the combination of the two agents on osteoclast apoptosis as a result of a noncompetitive nature of their signaling through the CaR. It is likely, therefore, that in patients with osteoporosis treated with strontium ranelate, Sr\(^{2+}\) and Ca\(^{2+}\) act together to inhibit bone resorption (Hurtel-Lemaire et al., 2009).

The idea that Sr\(^{2+}\) mediates its effects through the activation of the CaR has recently also been supported in a study by Fromigue et al. (2009), where it was shown that Sr\(^{2+}\) (in a ranolic acid form) rapidly increases ERK1/2 phosphorylation in osteoblasts expressing the CaR but not in osteoblasts from CaR knockout mice (Fromigue et al., 2009). It is noteworthy, however, that Ca\(^{2+}\), and Sr\(^{2+}\) increased cell replication and prevented cell apoptosis in osteoblasts from both CaR knockout mice and wild-type mice, indicating that Sr\(^{2+}\) can act independently of the CaR/ERK1/2 cascade to promote osteoblast proliferation. In addition, Sr\(^{2+}\) was shown to activate the Akt pro-survival pathway in osteoblasts from both wild-type and CaR knockout mice, and both the proliferative and antiapoptotic effects of Sr\(^{2+}\) were abolished by selective inhibition of COX-2, showing that in cells of the osteoblast lineage, in addition to the CaR, Sr\(^{2+}\) produces its effects through other pathways (Fromigue et al., 2009).

**Polyamines.** Polyamines, including spermine, spermidine, and putrescine (Fig. 3A), are cationic compounds known to activate the CaR, as has been demonstrated for instance in bovine parathyroid cells, where spermine (200 μM) was shown to inhibit PTH secretion by 50% (Quinn et al., 1997). Polyamines are found in a wide variety of tissues and are involved in stabilizing nucleic acid helical structure, having a role in cellular metabolism, growth, and differentiation. Polyamines also play a role in neurotransmission, producing their effects through modulation of the N-methyl-D-aspartic acid and α-amino-3-hydroxyl-5-methyl-4-isoxazolepropionate receptors and by blocking inwardly rectifying potassium channels (Shin et al., 2005; Kurata et al., 2007; de Vera et al., 2008).

Another important physiological role of polyamines is in the maintenance of the function of gastrointestinal epithelia, described to occur through the activation of the CaR expressed in different cell types present in the gastrointestinal tract (Ray et al., 1997; Cheng et al., 2004). Polyamines were described to mediate an increase in intracellular IP\(_3\) and Ca\(^{2+}\) accumulation in perfused colonic crypts, with the rank order spermine > spermidine > putrescine (Cheng et al., 2004), and in HEK293 cells transfected with the CaR (Quinn et al., 1997). In perfused colonic crypts, spermine was shown to inhibit both basal and forskolin-induced fluid secretion (Cheng et al., 2004). Increased Ca\(^{2+}\) concentrations were described to shift the EC\(_{50}\) for spermine to the left and, interestingly, subthreshold concentrations of spermine increased the sensitivity of CaR-expressing HEK293 cells to Ca\(^{2+}\), which is strongly suggestive of the involvement of the CaR (Quinn et al., 1997; Cheng et al., 2004). In the study by Cheng et al. (2004), it was reported that polyamine-induced effects required the presence of Ca\(^{2+}\). However, the requirement for Ca\(^{2+}\) was not supported in a study by Canaff et al. (2001), where spermine (1.25–20 mM) produced a concentration-dependent increase in Ca\(^{2+}\) in rat hepatocytes through the activation of the CaR in the absence of Ca\(^{2+}\) (Canaff et al., 2001), suggestive of being an orthosteric agonist. In addition to their actions in the colon, polyamines have also been described to produce Ca\(^{2+}\) mobilization and ERK1/2 activation using the human esophageal epithelial cell line (HET-1A) and in basal cells of the human esophagus, through the activation of the CaR (Justinich et al., 2008). Moreover, in G cells of the stomach, which express the CaR, spermine was shown to stimulate gastrin release in a concentration-dependent manner (Ray et al., 1997).

**Aminoglycoside Antibiotics.** Neomycin, gentamicin, and tobramycin (Fig. 3A), which belong to the group of AGAs, are known to activate the CaR. McLarnon et al. (2002) have compared the relative effects of different AGAs on Ca\(^{2+}\) increase using HEK293 cells transfected with the CaR (McLarnon et al., 2002). Neomycin, gentamicin, and tobramycin produced a concentration-dependent increase in Ca\(^{2+}\) with EC\(_{50}\) values of 43, 258, and 177 μM, respectively. These compounds were without effect in nontransfected cells. However, CaR agonism was shown not to be a feature common to all AGAs and kanamycin was ineffective at concentrations <1 mM. It is noteworthy that the rank order of potencies of the different AGAs correlates positively with the number of their attached amino groups, which may explain the lack of effect of kanamycin, which has the fewest attached amino groups (four, compared with five for gentamicin and trobymycin, and six for neomycin) (McLarnon et al., 2002).

It is important to understand the precise signaling of AGAs through the CaR, because these compounds produce an important adverse effect—nephrotoxicity. It has previously been described that the CaR contributes to this phenomenon (Ward et al., 2002). The proximal tubule-derived opossum kidney cells were shown to respond to elevated Ca\(^{2+}\) by neomycin, and gentamicin, with an increase in Ca\(^{2+}\), ERK1/2 activation, and phosphoinositide 3-kinase-dependent phosphorylation of Akt, glycogen synthase kinase 3β, and p38 MAPK (Ward et al., 2002, 2005). After a 4-day treatment with gentamicin, or other CaR agonists, the cells underwent cell death. Furthermore, gentamicin elicited significantly more cell death in HEK293 cells transfected with the CaR than in nontransfected cells (Ward et al., 2005). These results imply that the CaR is likely to contribute to signaling underlying the renal toxicity of AGAs.

**Allosteric Modulators of the CaR**

**Aromatic L-Amino Acids.** A feature common to all family 3 GPCRs, including the CaR, is the presence of amino acid binding sites in the VFTM (Conigrave et al., 2007). The family 3 of GPCRs includes receptors whose primary ligands are amino acids, such as the glutamate and GABA receptors and several receptors that act as broad-spectrum amino acid sensors (Wellendorf and Brauner-Osborne, 2009). The aromatic L-amino acids that have been reported to activate the CaR include L-Phe, L-Trp, L-Tyr, and L-histidine (Fig. 3B) (Conigrave et al., 2007), producing an allosteric modulation of CaR signaling in the presence of Ca\(^{2+}\). Some aliphatic L-amino acids also bind the CaR, such as L-leucine and poly-L-arginine (Brown et al., 1991; Busque et al., 2005).

The existence of an interaction between the CaR and amino acids is not very surprising, because it has been known for years that Ca\(^{2+}\) concentration and amino acid metabolism are linked. People with increased intake of aromatic amino acids have increased urinary Ca\(^{2+}\) excretion compared with people with similar increases in intake of branched-chain amino acids (Dawson-Hughes et al., 2007). In addition,
secondary HPT has been reported in subjects consuming low-protein diets, suggestive of an amino acid-sensing mechanism linked to the control of urinary Ca\(^{2+}\) excretion and PTH release (Conigrave et al., 2002).

The organ in which aromatic l-amino acids come into contact with the CaR, is the gastrointestinal tract, where these compounds regulate various functions, including the rate of gastric acid secretion from G cells of the stomach and acid-secreting parietal cells (Conigrave et al., 2002; Busque et al., 2005). Busque et al. (2005) have reported that L-Phe, L-Trp, and L-leucine produce a decrease in gastric luminal pH in ex vivo stomach preparations at physiological Ca\(^{2+}\) concentrations. Hira et al. (2008) have demonstrated in in vivo and in vitro studies that L-Phe stimulates cholecystokinin secretion and Ca\(^{2+}\) mobilization in enteroendocrine STC-1 cells, which express the CaR, in a concentration-dependent manner (Hira et al., 2008). This effect was augmented at elevated Ca\(^{2+}\)o concentrations and was inhibited by NPS 2143, a negative allosteric modulator of the CaR, suggestive of the involvement of the CaR (Hira et al., 2008). A confirmation that the CaR is involved in the functions of aromatic l-amino acids was described in a recent study by Lee et al. (2007) using HEK293 cells transfected with the CaR. This study showed that L-Phe and L-Trp enhance the Ca\(^{2+}\)o-induced increase in Ca\(^{2+}\) mobilization in CaR transfected cells, as well as in normal human parathyroid cells, but not in nontransfected HEK293 cells. L-Phe and L-Trp were also shown to induce a small but physiologically significant enhancement of Ca\(^{2+}\)o-dependent suppression of PTH secretion and ERK1/2 activation in parathyroid cells, producing a decrease in the EC\(_{50}\) of Ca\(^{2+}\)o (Lee et al., 2007). However, because of the small effects produced by aromatic l-amino acids on the various physiological effects, it is believed that these compounds are probably involved only in fine-tuning of CaR signaling.

**Synthetic Allosteric Modulators of the CaR.** Synthetic allosteric modulators of the CaR have recently been identified belonging to the phenylalkylamine group of compounds, with structural similarities to the naturally occurring CaR agonists, such as the aromatic l-amino acids, with an aromatic ring and positively charged amine groups (Fig. 3B). These ligands were synthesized with the aim of regulating PTH secretion in patients with HPT. Calcimimetics and calcilytics do not activate the wild-type CaR directly, but rather shift the concentration-response curves of Ca\(^{2+}\)o and other orthosteric agonists to the left or right, respectively (Ferry et al., 1997). As mentioned earlier, allosteric modulators of the CaR bind to the seven TM region of the CaR, not the ECD, which is the binding site for orthosteric ligands. CaR allosteric modulators that have been studied in some detail include the calcimimetics cinacalcet (Evenepoel, 2008), NPS R-568 (Harrington and Fotsch, 2007), and calindol (Petrel et al., 2004) and the calcilytics NPS 2143 (Gowen et al., 2000) and Calhex 231 (Petrel et al., 2003) (Fig. 3B). The identification of calcimimetics and calcilytics led to the realization that these compounds have a therapeutic potential for the treatment of various disorders associated with CaR malfunction, such as HPT and possibly osteoporosis, respectively. Calcilytic and calcimimetic compounds have advantages over conventional CaR ligands in that their effects are more specific because of their more limited range of targets. Other CaR agonists, such as divalent and trivalent cations, aromatic l-amino acids, and polyamines, produce their effects in addition to the CaR, via ion channels and various other receptors, such as GPRC6A, N-methyl-D-aspartic acid, and α-amino-3-hydroxyl-5-methyl-4-isoxazolepropionate.

**The Effect of pH and Ionic Forces on the Signaling of the CaR.** The activity of the CaR is modulated by pH\(_{o}\) (Quinn et al., 2004; Doroszewicz et al., 2005) and ionic strength (Quinn et al., 1998). This is not surprising, because all CaR agonists are cationic compounds, and their receptor binding occurs through electrostatic interactions with charged residues in the ECD of the CaR, including glutamic and aspartic acid residues, which can be modulated by physicochemical conditions of the extracellular milieu (Quinn et al., 2004).

The effects of pH\(_{o}\) on CaR’s sensitivity to Ca\(^{2+}\)o were observed at both decreased and increased pH\(_{o}\), deviating from the physiological pH\(_{o}\) of 7.4. At increased pH\(_{o}\), the CaR was more sensitive to activation by Ca\(^{2+}\)o and Mg\(^{2+}\)o, whereas a decrease in pH\(_{o}\) produced lower sensitivity (Quinn et al., 2004; Doroszewicz et al., 2005). However, when pH\(_{o}\) was decreased even further, to less than 5.5, CaR sensitivity to Ca\(^{2+}\)o was partially recovered. The pH\(_{o}\)-induced effect was CaR specific, and another GPCR, the thrombin receptor, was shown to be insensitive to changes in pH\(_{o}\) (Quinn et al., 2004).

In contrast, McLarnon et al. (2002) have shown that reducing pH\(_{o}\) from 7.4 to 6.9 to mimic the luminal pH of the renal proximal tubule, which express the CaR on the apical surface, enhanced the sensitivity of the CaR to tobramycin and elicited a greater increase in Ca\(^{2+}\)i. These findings suggest that decreasing pH\(_{o}\) has an opposite effect on AGAs compared with Ca\(^{2+}\)o and Mg\(^{2+}\)o. Furthermore, these results imply that AGAs may be more potent CaR agonists in the proximal tubule than anywhere else (McLarnon et al., 2002).

The discrepancy between the pH\(_{o}\)-induced effects on divalent cation signaling versus AGA signaling through the CaR may be explained by the resistance of the charges on Ca\(^{2+}\)o and Mg\(^{2+}\)o to pH. Thus, in the case of divalent cations, the pH\(_{o}\)-induced effect is produced mainly by modulation of the charged residues on the CaR; for example, the modulation of the positively charged histidine residues, which are present at high density in the ECD, may occur at elevated pH\(_{o}\). By contrast, in the case of polycationic compounds such as AGAs as well as polyamines and aromatic l-amino acids, which contain several primary amino groups, decreased pH\(_{o}\) may lead to their protonation, making the compounds more positively charged, thus activating the CaR to a greater extent. In addition, decreased pH\(_{o}\) on its own, in the absence of agonists is capable of activating the CaR, suggesting that H\(_{2}\)o is itself an agonist of this receptor (Quinn et al., 2004).

Moreover, H\(_{2}\)o may be capable of shifting the balance between active and inactive receptor states, favoring a receptor conformation, which produces constitutive activation. Thus, the sensitivity of the CaR to pH\(_{o}\) and the subsequent modulation of signaling may have physiological relevance in tissues that experience changes in pH\(_{o}\) including the stomach, the kidney, bone, and the brain, where an additional function of the CaR may be as a pH\(_{o}\) sensor.

In addition to pH\(_{o}\), ionic strength of the extracellular milieu also influences CaR activity. A study by Quinn et al. (1998) has described that changes in the concentration of external NaCl (or other salts) changed the activation of the
CaR by Ca\textsuperscript{2+} and spermine. Ionic strength had an inverse effect on the sensitivity of CaR to its agonists (Quinn et al., 1998); at lower ionic strength, the CaR was more sensitive to activation by Ca\textsuperscript{2+} and at higher ionic strength, it was less sensitive. In parathyroid cells, addition of 40 mM NaCl shifted the EC\textsubscript{50} for Ca\textsuperscript{2+} inhibition of PTH to the right by more than 0.5 mM. Thus, in addition to being a pH\textsubscript{o} sensor, the CaR may also act physiologically as an ionic strength sensor (Quinn et al., 1998).

**Agonist-Directed Signaling through the CaR**

It is now widely accepted that through the activation of the same receptor, different agonists are capable of producing agonist-specific active receptor states, leading to a bias in G protein selection and intracellular pathway activation, resulting in various physiological effects (Kenakin, 2007; Michel and Alewijnse, 2007; Aloyo et al., 2009). This concept is often referred to as “agonist-directed signaling” or “agonist-directed stimulus trafficking.”

As described above, due to the different binding sites of the various CaR ligands to the CaR, it is conceivable that differential CaR active conformations may be formed with preferential activation of different intracellular pathways (Fig. 4). For example, as noted earlier, the sensitivity of the CaR to Mg\textsuperscript{2+} changes depending on the cell type under study. Whereas in the parathyroid Mg\textsuperscript{2+} produces effects comparable with those of Ca\textsuperscript{2+} in the thyroid it is much less efficacious (Garrett et al., 1995). A possible explanation for this may be the unavailability or differential expression levels of the preferred G protein subtypes in certain cell types or the strength of stimulus, and weak signal through the CaR may result in the activation of only the most efficiently coupled G proteins.

Chattopadhyay et al. (2007) have reported that in HEK293 cells transfected with the CaR, the potency of Sr\textsuperscript{2+} varied depending on the biological response tested. Sr\textsuperscript{2+} was less potent than Ca\textsuperscript{2+} at stimulating IP\textsubscript{3} accumulation and at increasing Ca\textsuperscript{2+}, but was comparable with Ca\textsuperscript{2+} at stimulating ERK phosphorylation and opening of nonselective cation channel (Chattopadhyay et al., 2007). Whether differential modulation of the CaR by Ca\textsuperscript{2+} and Sr\textsuperscript{2+} is responsible for these differences is not certain, and differential activity of the two cations at ion channels could offer an alternative explanation (Chattopadhyay et al., 2007). Furthermore, as described above, differences in Sr\textsuperscript{2+} and Ca\textsuperscript{2+} signaling through the CaR have been described to occur in primary mature rabbit osteoclasts, where Sr\textsuperscript{2+}-induced apoptosis was shown to depend on PKC\textsubscript{βII} activation, whereas Ca\textsuperscript{2+}-induced effects were not. Furthermore, Sr\textsuperscript{2+} signaling was shown to be independent of the IP3 pathway, in contrast to Ca\textsuperscript{2+} signaling. Both agents produced stimulation of PLC and nuclear translocation of NF-κB (Hurtel-Lemaire et al., 2009).

Another example of differential CaR signaling with various agonists was proposed by Ziegelstein et al. (2006), who showed that human aortic endothelial cells responded to spermine, leading to the release of Ca\textsuperscript{2+} and an increase in nitric oxide production, whereas Ca\textsuperscript{2+}, Gd\textsuperscript{3+}, and neomycin were ineffective (Ziegelstein et al., 2006). The participation of the CaR in the spermine-induced effects was confirmed by the use of siRNA directed against the CaR, which abolished the response (Ziegelstein et al., 2006). Furthermore, with the addition of cinacalcet, a concentration-dependent vasodilation was reported in the precontracted aorta in a study by Smajilovic et al. (2007), whereas the CaR agonists neomycin and Gd\textsuperscript{3+} had no effect. Because the involvement of the CaR

![Fig. 4. Agonist-directed signaling through the CaR. A schematic representation of the various conformations of the intracellular regions of the CaR that result upon binding of different ligands. Depending on the conformation, differential activation of the available G proteins is mediated. The diagram represents the reported differences in CaR signaling upon activation by Ca\textsuperscript{2+}, Sr\textsuperscript{2+}, Ca\textsuperscript{2+}/cinacalcet or Ca\textsuperscript{2+}/NPS 2143. Based on the results obtained in the mature osteoclast, Ca\textsuperscript{2+} and Sr\textsuperscript{2+} may be able to trigger different intracellular signaling through the CaR. Ca\textsuperscript{2+} was shown to activate the PLCβ pathway with subsequent signaling via the IP\textsubscript{3}; in contrast, Sr\textsuperscript{2+} produced its effects in these cells through the PLCβ/DAG/PKCβII pathway, independently of the IP\textsubscript{3} (Hurtel-Lemaire et al., 2009). Using various cell types, it has been shown that calcimimetics (cinacalcet) and calclycitics (NPS 2143) increase and decrease Ca\textsuperscript{2+}-signaling through the CaR, respectively. The thickness of the arrows signifies the strength of pathway activation. Although this diagram is hypothetical, the G protein heterotrimers designated as G1 and G2 probably represent two different G\textsubscript{q/11} heterotrimers.](image-url)
was not confirmed in this study, this vasodilatory effect of cinacalcet may be mediated through a different mechanism, for example by a direct action on ion channels (Smajilovic et al., 2007). Another example of this phenomenon was demonstrated in a study by Bruce et al. (1999), where stimulation of pancreatic acinar cells with Ca$^{2+}$ and Gd$^{3+}$ produced Ca$^{2+}$ release, whereas neomycin had no effect (Bruce et al., 1999).

Other differences in CaR signaling by different CaR agonists include the nature of Ca$^{2+}$ release. Compared with elevated Ca$^{2+}$, which stimulates PLC-mediated production of IP$_3$ and causes sinusoidal oscillations in Ca$^{2+}$, aromatic L-amino acid-induced CaR activation does not stimulate PLC but promotes transient oscillations in Ca$^{2+}$ through a distinct mechanism involving the transient receptor potential cation channel 1 (Rey et al., 2006). Selective abolition of the sensitivity of the CaR to Ca$^{2+}$, indicating that the potency of the drug is dependent on Ca$^{2+}$, indicating that the potency of the drug is dependent on Ca$^{2+}$ (Ferry et al., 1997). Unfortunately, the clinical tests on this drug were discontinued because of its low bioavailability and high inter- and intraindividual variability (Shoback et al., 2003). After this, cinacalcet (AMG 073) was developed and clinical research has focused on this drug because of its superior pharmacokinetic properties. The efficacy of cinacalcet for the treatment of primary (Shoback et

Current Uses and Potential Therapeutic Applications of CaR Ligands

Sr$^{2+}$

Strontium ranelate, a Sr$^{2+}$ salt of ranelic acid, is a newly developed drug for the treatment of osteoporosis, currently marketed as Protelos or Protos by Servier. Ranelate in strontium ranelate acts as a vector for the introduction of Sr$^{2+}$ into the organism, allowing Sr$^{2+}$ to replace Ca$^{2+}$ (1:10) in the hydroxyapatite crystals. This drug is atypical among osteoporosis treatments in that it both increases deposition of new bone by osteoblasts and decreases bone resorption by osteoclasts, thus favoring bone formation. The effectiveness of this drug has been demonstrated by numerous previous studies (Tournis et al., 2006; Roux et al., 2008; Seeman et al., 2008). Roux et al. (2008) have reported that the risk of vertebral fractures is reduced by 35% in postmenopausal women, aged between 50 and 65 years, treated with strontium ranelate during a 4-year period. Similar results were reported in another study, using an older population with a mean age of 69 years, which showed that the risk of developing new vertebral fractures decreased by 41% over a 3-year period of strontium ranelate treatment, and this effect was apparent in the first year of treatment, with a 49% risk reduction (Tournis et al., 2006). In addition, in patients above the age of 74 years, the incidence of nonvertebral fractures was 16% lower in the strontium ranelate-treated group compared with the placebo group, and the risk of hip fractures diminished by 36% (Tournis et al., 2006). Furthermore, recent long-term studies (8 and 5 years) have reported a continued increase in bone mass density in strontium ranelate treated postmenopausal women and a reduced risk of fractures (Meunier et al., 2009; Reginster et al., 2009).

Calcimimetics

It has been shown that calcimimetic drugs, which amplify the sensitivity of the CaR to Ca$^{2+}$, can suppress PTH levels in a concentration-dependent manner, leading to a fall in blood Ca$^{2+}$ in different forms of HPT (Block et al., 2004; Peacock et al., 2005). Thus, they are likely to become a major therapy for the treatment of primary PTH in certain patients with parathyroid adenomas and carcinomas, and secondary PTH associated with renal failure.

HPT is characterized by several features, including increased secretion of PTH and an increase in the mass of parathyroid tissue. Primary HPT is the result of an increase in the mass of the parathyroid gland, which causes increased PTH secretion and subsequently hypercalcemia, for example in parathyroid tumors, and it can often be cured by the removal of the parathyroid gland. Secondary HPT, which occurs in chronic kidney disease, develops as a result of reduced Ca$^{2+}$, and calcitriol concentrations in serum and an increase in phosphorus concentrations, which, in combination, consequently lead to increased PTH secretion as a compensatory response. The treatments for secondary HPT that have been available until now include vitamin D and calcium-containing phosphate binders (Komaba et al., 2008). Although these treatments have beneficial effects, they also have many disadvantages. Calcium-containing phosphate binders raise Ca$^{2+}$ and lower phosphate, whereas vitamin D increases serum concentrations of Ca$^{2+}$, and phosphate and lowers PTH. Ca$^{2+}$ has an antiproliferative effect in the parathyroid, leading to decreased proliferation of parathyroid cells. However, patients treated with high doses of these compounds often display hypercalcemia and, in the case of vitamin D, hyperphosphatemia as well. In hemodialysis patients, an imperfect management of serum PTH, Ca$^{2+}$, phosphorus and the Ca$^{2+}$ × phosphorus product can lead to serious consequences, especially an increased risk of cardiovascular and other soft tissue calcifications (Goodman, 2004). Therefore, better therapeutic agents are required for the treatment of HPT associated with chronic renal failure. Phenylalkylamine calcimimetics may be the answer to this problem. Due to the increase in the sensitivity of the CaR to Ca$^{2+}$ by calcimimetics, these compounds may be very beneficial under the circumstances of both primary and secondary HPT, which are characterized by decreased sensitivity of CaR to Ca$^{2+}$ (Tfelt-Hansen and Brown, 2005).

Initial studies have investigated the efficacy of the calcimimetic NPS R-568 for the treatment of HPT. Silverberg et al. (1997) have demonstrated that this compound reduces both serum PTH and Ca$^{2+}$, in patients with primary HPT in a concentration-dependent manner (Silverberg et al., 1997). In parallel, in rats it has been demonstrated that NPS R-568 also reduces proliferation of parathyroid cells in uremic HPT. In vitro studies have shown that in the presence of 1.3 mM Ca$^{2+}$, the potency of NPS R-568 at augmenting the IP$_3$ response in both CHO cells transfected with rat brain CaR and A7r20 cells with endogenous CaR was in the micromolar range. In both cell types, the IP$_3$ concentration-response curves of NPS R-568 were shifted to the left in the presence of increasing Ca$^{2+}$, indicating that the potency of the drug is dependent on Ca$^{2+}$ (Ferry et al., 1997). Unfortunately, the clinical tests on this drug were discontinued because of its low bioavailability and high inter- and intraindividual variability (Shoback et al., 2003). After this, cinacalcet (AMG 073) was developed and clinical research has focused on this drug because of its superior pharmacokinetic properties. The efficacy of cinacalcet for the treatment of primary (Shoback et
al., 2003; Peacock et al., 2005), and secondary HPT (Block et al., 2004) was demonstrated, as described below.

In a study by Shoback et al. (2003), the effectiveness of cinacalcet was confirmed in a short term study of 15 days in patients with primary HPT, showing that serum Ca\(^{2+}\) was normalized after 1 day of cinacalcet treatment and remained in the normal range for the duration of the study. In addition, reduced PTH levels were also reported. These results were later confirmed by Peacock et al. (2005) in a long-term double-blind placebo-controlled study. Oral cinacalcet was shown to rapidly normalize serum Ca\(^{2+}\), and produce a small decrease in PTH (7.6% decrease compared with 7.7% increase in placebo patients) in primary HPT patients (Peacock et al., 2005). These effects were maintained for the duration of the 52-week study. In addition, serum phosphorus was also increased, and cinacalcet was shown to decrease tubular Ca\(^{2+}\) reabsorption (Peacock et al., 2005). A recent study by Maroccoci et al. (2009) has demonstrated that cinacalcet also produces beneficial effects in patients with persistent primary HPT that have undergone parathyroidec- tomy, leading to a decrease in serum Ca\(^{2+}\) levels, thus showing its applicability in this setting (Maroccoci et al., 2009). Thus, cinacalcet treatment may be especially interesting for the treatment of primary HPT, because this disorder, although accompanied by increased serum Ca\(^{2+}\) levels, can otherwise be asymptomatic. Therefore, calcimimetics may provide a noninvasive way to normalize serum Ca\(^{2+}\) levels, providing a nonsurgical alternative.

The effectiveness of cinacalcet for the treatment of secondary HPT has also been described previously (Goodman et al., 2002; Lindberg et al., 2003; Quarles et al., 2003; Sprague et al., 2009). Cinacalcet was shown to be effective for this purpose in short-term studies (Goodman et al., 2002; Quarles et al., 2003). After conducting a 14-week study, Block et al. (2004) reported a 43% decrease in serum PTH in patients with secondary HPT receiving cinacalcet, compared with a 9% increase in the placebo group (Block et al., 2004). A 15% decrease in serum Ca\(^{2+}\) × phosphorus product was seen in the cinacalcet group, compared with no change in the placebo group. In another 18-week study, in which patients with secondary HPT and end-stage renal disease were treated with up to 100 mg of cinacalcet daily, the mean level of PTH in serum decreased by 33% compared with a slight increase (3%) in PTH in placebo patients (Quarles et al., 2003). In addition, the Ca\(^{2+}\) × phosphorus product decreased by 7.9% in cinacalcet-treated patients compared with a 11.3% increase in placebo-treated patients (Quarles et al., 2003). The decrease in Ca\(^{2+}\) × phosphorus product was confirmed by Lindberg et al. (2003), who reported an 11.9% decrease in cinacalcet-treated patients, compared with a 10.9% increase in placebo subjects after 18 weeks of treatment (Lindberg et al., 2003). The authors also reported a 26% reduction in PTH in cinacalcet-treated (50 mg/day), compared with a 22% increase in the placebo group of hemodialysis patients with secondary HPT. A recent study by Chonchol et al. (2009) reported a 43.1% decrease in intact PTH in cinacalcet-treated patients in a double-blind 32-week study (Chonchol et al., 2009). In addition, another recent study has demonstrated that the beneficial effects of cinacalcet are maintained over three years, with decreased PTH and Ca\(^{2+}\) × phosphorus levels (Sprague et al., 2009). The confirmed decrease in Ca\(^{2+}\) × phosphorus product implies that cinacalcet may produce beneficial effects in HPT by decreasing vascular calcifications (Quarles et al., 2003; Block et al., 2004; Aladrén Regidor, 2009). The reduction in the Ca\(^{2+}\) × phosphorus product is probably due to decreased PTH-driven Ca\(^{2+}\) and phosphorus efflux from bone. Because PTH is capable of directly stimulating Receptor Activator for NF-κB ligand-mediated osteoclast maturation, its decrease will result in reduced bone resorption. However, because the CaR is expressed in bone cells, osteoclasts, and osteoblasts, a direct effect of cinacalcet on the CaR expressed by these cells may provide another explanation for the reduced Ca\(^{2+}\) and phosphorus levels.

These cumulative studies have led to the approval of cinacalcet in 2004 in Europe, North America and Australia for the treatment of HPT, with trade names Mimpara in Europe and Sensipar in North America and Australia. It is the first positive allosteric modulator of any GPCR to be approved for therapeutic use. Based on the studies conducted so far, cinacalcet appears to be safe with no major side effects. Other calcimimetic agents from novel families of compounds have also been described previously (Kessler et al., 2004). Thus, although the research on calcimimetics continues, there is already ample evidence that these compounds have an important role in the treatment of HPT, and possibly other diseases in which CaR sensing is dysregulated, such as FHH and NSHPT.

Calcilytics

On the other hand, calcilytics, such as NPS 2143 and Calhex 231, shift the concentration-response curves of Ca\(^{2+}\) to the right (Kessler et al., 2006; Huang and Breitwieser, 2007) and they directly increase PTH secretion and indirectly raise plasma Ca\(^{2+}\) concentrations and urinary phosphate excretion. Therefore, because of the anabolic effects of PTH on bone, calcilytics have been suggested to have a potential in the prevention and treatment of osteoporosis (Arey et al., 2005). Calcilytics are currently being assessed for their ability to induce a “pulse” in the serum PTH concentration, thus mimicking the “pulse” resulting from injection of PTH, a known anabolic form of treatment for osteoporosis (Brown, 2007).

Calcilytics may also have a role in the treatment of hypoparathyroidism, as occurs in patients with an underactive parathyroid gland and in ADH. In addition, it has recently been hypothesized that these compounds may have a role in the treatment of certain cancers. For example, it has been described that the CaR is involved in bone metastases of prostate and breast cancer cells (Liao et al., 2006; Mihai et al., 2006), in part because of its role in the perpetuation of the vicious cycle in the bone, created by the parathyroid hormone-related peptide (Powell et al., 1991; Sanders et al., 2001). Activation of the CaR by Ca\(^{2+}\), leads to the release of parathyroid hormone-related peptide, which is believed to be a mediator in approximately 70% of malignant osteolysis in breast and prostate cancers, resulting in further release of Ca\(^{2+}\) and tumor growth-promoting factors. Thus, in this setting, antagonizing the CaR by the use of calcilytics may decrease the incidence of bone lesions, which is the primary contributor to the mortality of these cancers (Coleman, 1997). However, because of the contrasting effects of these agents compared with calcimimetics, one of the adverse effects that may arise through the use of calcilytics is an increased risk of developing vascular calcifications.
