ABSTRACT

The voltage-activated T-type calcium channel (CaV3.2) and the G protein-coupled neurokinin 1 (NK1) receptor are expressed in peripheral tissues and in central neurons, in which they participate in diverse physiological processes, including neurogenic inflammation and nociception. In the present report, we demonstrate that recombinant CaV3.2 channels are reversibly inhibited by NK1 receptors when both proteins are transiently co-expressed in human embryonic kidney 293 cells. We found that the voltage-dependent macroscopic properties of CaV3.2 currents were unaffected during NK1 receptor-mediated inhibition. However, inhibition was attenuated in cells coexpressing either the dominant-negative Gαq Q209L/D277N or the regulator of G protein signaling (RGS) 2 (RGS2) and 3T (RGS3T), which are effective antagonists of Gαq/11. By contrast, inhibition was unaffected in cells coexpressing human rod transducin (Gαι), which buffers Gβγ. Channel inhibition was blocked by 1-[6-[[17β-methoxyestra-1,3,5(10)-trien-17-yl]amino]hexyl]-1H-pyrrole-2,5-dione (U73122) and bisindolylmaleimide I, selective inhibitors of phospholipase Cβ and protein kinase C (PKC), respectively. Inhibition was occluded by application of the PKC activator phorbol-12-myristate-13-acetate. Altogether, these data indicate that NK1 receptors inhibit CaV3.2 channels through a voltage-independent signaling pathway that involves Gαq/11, phospholipase Cβ, and PKC. Our results provide novel evidence regarding the mechanisms underlying T-type calcium channel modulation by G protein-coupled receptors. Functional coupling between CaV3.2 channels and NK1 receptors may be relevant in neurogenic inflammation, neuronal rhythmogenesis, nociception, and other physiological processes.

ABBREVIATIONS: NK1, neurokinin 1; PKC, protein kinase C; NKA, neurokinin A; HNK1, human embryonic kidney; EGFP, enhanced green fluorescent protein; GPCR, G-protein coupled receptor; Gαi, rod transducin; RGS, regulator of G protein signaling; Bis, bisindolylmaleimide; PLC, phospholipase C; PMA, phorbol-12-myristate-13-acetate; U73122, 1-[6-[[17β-methoxyestra-1,3,5(10)-trien-17-yl]amino]hexyl]-1H-pyrrole-2,5-dione; SP, substance P; DRG, dorsal root ganglion.
tivation of muscarinic receptors evoked either stimulation or inhibition of nickel-sensitive T-type currents in embryonic rat hippocampal neurons (Toselli and Lux, 1989) or human granulosa cells (Platano et al., 2005), respectively. Likewise, activation of SP receptors attenuated T-type currents in rat nucleus basalis neurons (Margeta-Mitrovic et al., 1997), whereas SP receptors increased T-type currents in rat spinal dorsal horn neurons (Ryu and Randic, 1990). Application of the PKC activator phorbol-12-myristate-13-acetate (PMA) stimulated T-type currents in neonatal rat ventricular myocytes (Furukawa et al., 1992) but inhibited T-type currents in both newborn rat dorsal root ganglion neurons (Schroeder et al., 1990) and MN9D dopaminergic cells (Kim et al., 2007). Other activators of PKC, such as 1-oleoyl-2-acetyl-sn-glycerol and phorbol-12,13-didecanoate inhibited T-type channels in chick embryo dorsal root ganglion (DRG) neurons (Marchetti and Brown, 1988) and mouse thalamic neurons (Cheong et al., 2008), respectively. Thus, there is currently much uncertainty regarding the modulatory effects of a particular G-protein-coupled receptor on an identified T-type channel.

Expression of recombinant channels with identified receptors provides an alternative approach that reduces the number of variables inherent to native systems. Heterologous coexpression of cDNAs encoding a single variety of voltage-gated Ca\(^{2+}\) channels with a single receptor type has yielded valuable insights into the modulation of both high-voltage-activated Ca\(_v\) channels (Teford and Zamponi, 2006) and low-voltage-activated Ca\(_v\)3 channels (Iftinca and Zamponi 2009). However, the signaling pathways that modulate Ca\(_v\)3 channels and the effects that such modulation may have upon physiological processes remain incompletely characterized.

Although it is generally accepted that both Ca\(_v\)3.2 channels and NK1 receptors are expressed in peripheral and central neurons and that both participate in neurogenic inflammation and nociceptive transmission, no functional interaction between these two proteins has been reported previously. Here, we demonstrate that stimulation of NK1 receptors reversibly inhibits recombinant Ca\(_v\)3.2 channels expressed in human embryonic kidney (HEK) 293 cells. Inhibition is voltage-independent and requires signaling by Go_{q111}, phospholipase C\(_{\beta}\), and PKC.

**Materials and Methods**

**Cell Culture and Transfection.** HEK293 cells were obtained from the American Type Culture Collection (Manassas, VA) and maintained at 37°C in a humidified air atmosphere containing 5% CO\(_2\). The culture medium contained 90% Dulbecco’s modified Eagle’s medium (Invitrogen, Carlsbad, CA), 10% fetal bovine serum (Invitrogen), 100 U/ml penicillin, and 100 \(\mu\)g/ml streptomycin. Once a week, cells of low passage number (<20) were replated at low density (20–30% coverage) on 35-mm culture dishes and transfected within 3 to 5 days using Ca\(_{\text{a}}\)(PO\(_4\))\(_2\) precipitation technique (CellPhet Kit; GE Healthcare, Chalfont St. Giles, Buckinghamshire, UK). The transfection mixture included expression plasmids encoding Ca\(_{v}\)3.2 calcium channel subunit (at 1.0 \(\mu\)g/dish) and separate plasmids that encoded the NK1 receptor (1.0 \(\mu\)g/dish) and enhanced green fluorescent protein (EGFP) (0.1 \(\mu\)g/dish). In selective experiments, transfection mixture was added with either rod transducin (Go) (1.0 \(\mu\)g/dish) or the dominant-negative Go\(_{q}\) Q209L/D277N (GenBank accession AF051946) was in pcDNA3.1 (Invitrogen). Human NK1 receptor (GenBank accession number NM_015727) was in pCI (Promega, Madison, WI). Jellyfish enhanced green fluorescent protein (GenBank accession number U55763) was in pEGFP (Clontech, Cambridge, UK). Human RGS2 (GenBank accession number U27655) was in pEGFP-C3 (Clontech). Human RGS2 (GenBank accession number L13463) was in pEGFP-C2 (Clontech). Human rod transducin (GenBank accession number X63749) was in pcDNA3.1. Human dominant-negative Go\(_{q}\) Q209L/D277N (GenBank accession number U40038) was in pcDNA3.1. The last construction was obtained from the University of Missouri–Rolla cDNA resource center (Rolla, MI).

**Voltage-Clamp Recordings.** Large-bore patch pipettes were pulled from 100-\(\mu\)l borosilicate glass micropipettes (World Precision Instruments, Inc., Sarasota, FL) and filled with an intracellular solution containing 155 mM CsCl, 10 mM Cs\(_{\text{EGTA}}\), 4 mM Mg\(_{\text{ATP}}\), 0.32 mM Li\(_{\text{GTP}}\) and 10 mM HEPES, with pH adjusted to 7.4 with CsOH. Aliquots of pipette solution were stored at \(-80°C, kept on ice.

**Fig. 1.** Inhibition of Ca\(_v\)3.2 channels by NK1 receptors. A, whole-cell Ca\(^{2+}\) currents recorded in the absence or presence of 10 nM NKA. Currents were evoked by voltage steps from \(-90\) to \(-20\) mV at 0.1 Hz. Cell capacitance (\(C_{\text{m}}\)) = 21.0 pF and series resistance (\(R_s\)) = 2.5 M\(\Omega\). B, time course of the inhibitory effect of NKA. The peak current amplitude was plotted as a function of time. Application of NKA is indicated by a horizontal bar; the same current amplitude was added (\(n = 4–8\)). The solid line corresponds to the fit of the average data to the Hill equation: \(I_{\text{C0}}(\% \text{ inhibition}) = D[1+(NKA/IC_{50})^h]\), where D represents maximal percent of inhibition, IC\(_{50}\) is the NKA concentration producing half-maximal inhibition, and \(h\) is the Hill coefficient.

---

**Expression Plasmids.** Human Ca\(_{v}\)3.2 (\(\alpha_{q11}\)) (GenBank accession number AF051946) was in pcDNA3.1 (Invitrogen). Human NK1 receptor (GenBank accession number NM_015727) was in pCI (Promega, Madison, WI). Jellyfish enhanced green fluorescent protein (GenBank accession number U55763) was in pEGFP (Clontech, Cambridge, UK). Human RGS2 (GenBank accession number U27655) was in pEGFP-C3 (Clontech). Human RGS2 (GenBank accession number L13463) was in pEGFP-C2 (Clontech). Human rod transducin (GenBank accession number X63749) was in pcDNA3.1. Human dominant-negative Go\(_{q}\) Q209L/D277N (GenBank accession number U40038) was in pcDNA3.1. The last construction was obtained from the University of Missouri–Rolla cDNA resource center (Rolla, MI).
Fig. 2. The inhibitory effect of NKA on CaV3.2 channels is voltage-independent. A, current families recorded from the same cell before (top) or after application of 10 nM NKA (bottom). Currents were generated by depolarizations from −90 to −60 through +30 mV in 10-mV steps at 0.1 Hz. $C_m = 17.8 \mu F$, and $R_s = 3.3 \Omega m$. B, normalized current-voltage (I-V) curve of CaV3.2 channels determined before (○) or during (●) NKA application. Voltage protocol is as described in A. I-V curves were normalized to maximal control peak current amplitude for each cell. A scaled I-V curve during NKA application (□) is also shown for comparison. The maximal voltage error was 3.6 ± 0.4 mV ($n = 8$). C, currents evoked by a test pulse to −20 mV after a 2-s prepulse to the indicated potentials were recorded from the same cell before (top) or after the application of NKA (bottom). $C_m = 11.3 \mu F$ and $R_s = 4.5 \Omega m$. D, normalized activation and steady-state inactivation curves in the absence (○) or presence (●) of NKA. Voltage protocol is as described in A and C, respectively. The normalized conductance values were obtained for each cell by the chord conductance method; the same cells as in B. The
after thawing, and filtered at 0.22 μm immediately before use. Filled pipettes had resistances of 1.2 to 1.5 MΩ. The bath solution contained 185 mM NaCl, 10 mM CaCl₂, 2 mM KCl, and 10 mM HEPES, with pH adjusted to 7.4 with NaOH. After forming a gigaohm seal in the cell-attached configuration, residual pipette capacitance was compensated using the negative capacitance compensation circuit of the Axopatch 200B patch-clamp amplifier (Molecular Devices, Sunnyvale, CA). No corrections were made for liquid junction potentials. Ca²⁺ currents were recorded in the whole-cell, ruptured-patch mode. The steady holding potential in all of the experiments was −90 mV. Test depolarizations were delivered at 0.1 to 0.2 Hz. Macrosopic Ca²⁺ currents were filtered at 2 to 5 kHz using the built-in Bessel filter (four-pole low-pass) of the amplifier and sampled at 10 kHz using a Digidata 1200 analog-to-digital converter (Molecular Devices) installed in a personal computer. The pCLAMP software programs Clampex and Clamppfit (version 9.2; Molecular Devices) were used for data acquisition and analysis, respectively. Figures, data fits, and statistical comparisons were performed using the software program Origin (versions 6.0 and 7.5; OriginLab Corp, Northampton, MA). Series resistance (Rₛ), linear cell capacitance (Cₘ), and time constant for decay of the whole-cell capacity transient (τ) values were determined directly from readings on the amplifier. Rₛ was measured for each cell by using the series resistance compensation circuit of the amplifier. The average value of Cₘ was 19.1 ± 0.7 pF (mean ± S.E.M.; n = 143). The average values of compensated τ and Rₛ were 61.5 ± 5 μs and 3.5 ± 0.1 MΩ, respectively. The Ca²⁺ currents were typically evoked by step depolarizations from −90 to −20 mV. The average maximum current, measured at the time of peak inward current for each cell, was 1.0 ± 0.6 nA, and the corresponding average maximal voltage error was 3.3 ± 0.1 mV. The resistance of the whole-cell configuration was typically >1 GΩ. The Ca²⁺ currents were corrected for linear capacitance and leakage currents using −P₄ subtraction. All experiments were performed at room temperature (20–23°C).

Reagents. NKA, bisindolylmaleimide (Bis) I, Bis V, and PMA were purchase from Calbiochem (San Diego, CA). NKA was dissolved in 5% acetic acid to make a 1.0 mM stock solution, separated into aliquots, and stored at −80°C. Bis I and Bis V were dissolved in dimethylsulfoxide to make 2.5 and 3.0 mM stock solutions, respectively, separated into aliquots, and stored at 4°C. PMA was dissolved in ethanol to make 1.5 mM stock solution, separated into aliquots, and stored at −20°C. The final concentration of all the vehicles was always <0.001%, which did not significantly modify the basal properties of CaV₃.2 channel or its modulation by NKA.

Data Analysis. Results are reported as mean ± S.E.M. Treatment residuals were tested for homogeneity of variances and normality using the Brown-Forsythe and Shapiro-Wilk procedures, respectively. Means were compared using one-tailed unpaired Student’s t test, single population test, or one-way analysis of variance, as indicated. Statistical significance was set at p < 0.05. For multiple comparisons using successive t test, α was maintained at the 0.05 level using the Bonferroni correction. The experimental design corresponded to generalized random blocks, in which the blocking criterion was the cell transfection.

Results

CaV₃.2 Currents Are Inhibited through Activation of NK₁ Receptors. It has been shown previously that T-type CaV₃.2 channels are modulated by several different types of heteromeric G protein-coupled receptors (Welsby et al., 2003; Wolfe et al., 2003; Kim et al., 2006, 2007; Iftinca et al., 2007; Tao et al., 2008). However, little is currently known regarding the modulation of T-type channels by tachykinin receptors. This is a significant issue because T-type channels and tachykinin receptors both play important roles in diverse physiological processes, including neurogenic inflammation and nociception. To address this gap in knowledge, we investigated the effects of activation of NK₁ receptors on CaV₃.2 channels. We used the natural agonist NKA, because this peptide functions as a full agonist for NK₁ receptors (Pennefather et al., 2004), yet its effects are easily reversible upon washout. As illustrated in Fig. 1A, 10 nM NKA inhibited CaV₃.2 currents by 23.9 ± 1.3% (n = 59, p < 0.05). Inhibition was maintained throughout NKA applications and was fully relieved after washout (Fig. 1B). No evidence for receptor desensitization was observed during NKA applications lasting up to 3 min, in agreement with our previous report (Meza et al., 2007). As shown in Fig. 1C, NKA generated a dose-dependent inhibition of CaV₃.2 channels. The averaged normalized dose-response data were fitted with a Hill equation, yielding an IC₅₀ value of 0.62 nM and a Hill coefficient value of 0.56. It is noteworthy that NKA did not affect CaV₃.2 currents in cells not transfected with the NK₁ receptor (data not shown). These results demonstrate that CaV₃.2 channels are reliably and reversibly inhibited through NK₁-dependent activation of NK₁ receptors.

NK₁ Receptors Produce Voltage-Independent Inhibition of CaV₃.2 Currents. Modulation of CaV₃.2 channels by G protein-coupled receptors may involve voltage-dependent and/or voltage-independent mechanisms (Tedford and Zamponi, 2006; Iftinca and Zamponi, 2009). Therefore, we assessed the voltage-dependence of inhibition of CaV₃.2 channels by NK₁ receptors. Figure 2A shows representative CaV₃.2 currents generated by a series of test pulses in the absence or presence of 10 nM NKA. A similar degree of inhibition was observed at all test potentials, suggesting that inhibition of CaV₃.2 by NKA was predominantly voltage-independent. Accordingly, the normalized current-voltage and conductance-voltage relationships, obtained both before and after the application of NKA, were not different (Fig. 2, B and D). The corresponding mean values of V₁/₂ for maximal conductance were −31.3 ± 1.4 and −32.8 ± 1.8 mV in the absence and presence of NKA, respectively (n = 9; p > 0.05). The values of the slope factor were 6.6 ± 0.3 and 6.5 ± 0.4 mV before or after NKA, respectively (p > 0.05). Likewise, the normalized steady-state voltage-dependent inactivation relationship was not modified by NKA (Fig. 2, C and D). The corresponding values of V₁/₂ for maximal steady-state inactivation were −54.8 ± 0.8 and −55.6 ± 2.1 mV, before and after application of NKA, respectively (n = 5; p > 0.05). The values of slope factor were 5.2 ± 0.5 and 6.0 ± 1.0 mV in the absence or presence of NKA, respectively (p > 0.05). Finally, we looked for the effects of NKA on activation and inactiva-
tion kinetics of CaV3.2 currents. Neither the activation nor inactivation rate was modified by NKA at any test potential (Fig. 2, E and F). Altogether, these data indicate that inhibition of macroscopic CaV3.2 currents by NK1 receptors does not involve significant changes in channel voltage-dependence. Thus, NK1 receptor activation produces a voltage-independent inhibition of CaV3.2.

**Gαq11 Subunits Mediate the Inhibition of CaV3.2 by NK1 Receptors.** It is well known that NK1 receptors mainly couple to heterotrimeric Gq/11 proteins (Macdonald et al., 1996). Accordingly, we reported recently (Meza et al., 2007) that both Gq/11 and Gβγ subunits are involved in mediating a complex modulation of CaV2.3 (R-type) calcium channels by NK1 receptors. To examine this question for CaV3.2, the dominant-negative Gαq Q209L/D277N (Kumar et al., 2008), or the scavenger proteins for either Gq/11 subunits (i.e., RGS2 or RGS3T) (Kammermeier and Ikeda, 1999; Meza et al., 2007) or Gβγ subunits (i.e., rod transducin) (Meza et al., 2007), were separately expressed with CaV3.2 channels and NK1 receptors in HEK293 cells. In cells expressing the dominant-negative Gαq Q209L/D277N, inhibition of CaV3.2 currents by NKA was reduced to 7.3 ± 1.4% (n = 8) compared with 16.0 ± 3.1% (n = 9) in matching control cells (p < 0.05). In cells that expressed RGS3T, inhibition was reduced to 6.4 ± 2.1% (n = 6) compared with 30.3 ± 6.1% (n = 6) in matching control cells (p < 0.05) (Fig. 3, A–C). Likewise, inhibition was significantly reduced in cells expressing Gαq (19.8 ± 3.2%, n = 11, versus 24.9 ± 3.3%, n = 11 in matched controls; p < 0.05) (Fig. 3, D–F). These data suggest that inhibition of CaV3.2 channels by NK1 receptors requires signaling by Gαq11 but not Gβγ.

**Inhibition of CaV3.2 Currents by NK1 Receptors Requires PKC.** Studies have reported that CaV3.2 channels are modulated by signaling through PLC and protein kinase C (PKC) (Park et al., 2003, 2006; Chemin et al., 2007). To explore this subject in relation to CaV3.2 inhibition by NKA, cells that expressed both CaV3.2 channels and NK1 receptors were preincubated in culture medium containing 3 μM U73122, a specific inhibitor of PLC (Kumar et al., 2008). As illustrated in Fig. 4, A to C, inhibition of CaV3.2 currents by NKA was significantly attenuated in these cells (7.8 ± 1.7%, n = 7) compared with cells preincubated in vehicle (16.0 ± 0.8%, n = 7, p < 0.001). In addition, when 200 nM PMA, a well known activator of PKC (Kim et al., 2007), was directly applied in the bath, CaV3.2 currents were inhibited to an extent (25.9 ± 4.3%, n = 8) indistinguishable from that produced by application of 10 nM NKA (21.6 ± 2.5%, n = 8, matching control cells (p < 0.05) (Fig. 3, A–C). Likewise, inhibition was significantly reduced in cells that expressed RGS2 (15.2 ± 2.1%, n = 12, versus 24.7 ± 2.0%, n = 12 in matching controls; p < 0.05). In contrast, the magnitude of inhibition was not significantly reduced in cells expressing Gαq (19.8 ± 3.2%, n = 11, versus 24.9 ± 3.3%, n = 11 in matched controls; p > 0.05) (Fig. 3, D–F). These data suggest that inhibition of CaV3.2 channels by NK1 receptors requires signaling by Gαq11 but not Gβγ.
Furthermore, channel inhibition by NKA was completely occluded by preapplication of PMA (Fig. 4, D and E). Thus, the average percentage of inhibition induced by simultaneous addition of PMA and NKA (22.0 ± 3.7) was not significantly different from that evoked by PMA alone (25.9 ± 4.3, n = 8; p > 0.05) (Fig. 4F), suggesting that both reagents were acting through a common signaling element (i.e., PKC). Finally, inhibition of CaV3.2 currents by NKA was significantly attenuated (6.1 ± 1.6%, n = 8, p < 0.05) in cells preincubated in 500 nM Bis I, a specific inhibitor of PKC (Sculptoreanu and de Groat, 2003) (Fig. 4, G–I), whereas inhibition was not significantly reduced in cells preincubated in 500 nM Bis V (21.1 ± 3.2%, n = 8, p > 0.05), the inactive analog of Bis I. Altogether, these results indicate that NK1 receptors inhibit CaV3.2 channels by inducing signaling by PLCβ and PKC.

**Discussion**

It is known that T-type calcium channels in different cell types (expressed endogenously or heterologously) are modulated by diverse hormones and neurotransmitters acting through heterotrimeric G protein-coupled receptors, but the molecular mechanisms involved remain largely uncharacterized. In this study, we report that recombinant T-type CaV3.2 channels, transiently expressed in HEK293 cells, are reversible inhibited by Gq/11-coupled NK1 receptors via a voltage-independent and PKC-mediated signaling pathway.

Previous studies have demonstrated that CaV channels are modulated (either enhanced or inhibited) by neurokinin receptors in various types of neurons, such as rat spinal dorsal horn neurons (Ryu and Randic, 1990), rat nucleus basalis neurons (Margeta-Mitrovic et al., 1997), rat dorsal root gan-

**Fig. 4.** Inhibition of CaV3.2 by NKA requires PKC. A. inhibition is sensitive to U73122. CaV3.2 currents were recorded before or after the application of 10 nM NKA from a cell that was preincubated in culture medium containing 3 μM U73122 for 1 h at 37°C. Currents were evoked by a voltage step from −90 to −20 mV at 0.1 Hz. Cm = 21.4 pF, and Rs = 2.9 MΩ. B, time course of the inhibitory effect of NKA on the same cell as in A. C, pooled data for CaV3.2 current inhibition by NKA in control cells (n = 7) or cells that were preincubated with U73122 (n = 7, ***p < 0.001). D, currents recorded under control conditions, during the addition of 100 nM PMA, or after the application of NKA in the presence of PMA. Test pulse protocol as in A. Cm = 32.9 pF, and Rs = 1.7 MΩ. E, time course of the inhibitory effect of NKA on the same cell as in D. Note the lack of effect of NKA when it was applied during the maximum steady-state inhibitory effect of PMA. F, pooled data for CaV3.2 current inhibition by 10 nM NKA (n = 8), 100 nM PMA (n = 8), or 100 nM PMA + 10 nM NKA (n = 8, p > 0.05). G, inhibition of CaV3.2 current by NKA is sensitive to Bis I. Currents were recorded, before or after application of 10 nM NKA, from a cell that was preincubated in culture medium containing 500 nM Bis I for 1 h at 37°C. Same test pulse protocol as in A. Cm = 28.9 pF, and Rs = 2.2 MΩ. H, time course of the inhibitory effect of NKA on the same cell as in G. I, pooled data for CaV3.2 current inhibition by NKA in control cells (n = 8) or cells preincubated with 500 nM Bis I (n = 8) or 500 nM Bis V (n = 8, *p < 0.05). Bis I versus control and Bis V.
glion neurons (Sculptoreanu and de Groat, 2003), and rat nucleus tractus solitarius neurons (Endoh, 2006). We have reported that NK1 receptors induced a pertussis toxin- and cholera toxin-insensitive G\textsubscript{q/11}-mediated modulation of high-voltage-activated Ca\textsubscript{v}.2.3 channels coexpressed in HEK293 cells through a complex mechanism that involved a fast G\textsubscript{\beta\gamma}-mediated inhibition and both slow inhibition and slow stimulation mediated by G\textsubscript{q/11} subunits (Meza et al., 2007). Our present results indicate that NK1 receptors evoked an inhibition of T-type Ca\textsubscript{v}.3.2 channels mediated by G\textsubscript{q/11} proteins via G\textsubscript{q/11} subunits that was independent from signaling by G\textsubscript{\beta\gamma}. This conclusion is supported by the ability of the dominant-negative G\textsubscript{\alpha} Q209L/D277N, RGS2, and RGS3T, but not G\textsubscript{\alpha}, to attenuate inhibition of Ca\textsubscript{v}.3.2 by NKA (Fig. 3). The absence of a G\textsubscript{\beta\gamma}-mediated attenuation of Ca\textsubscript{v}.3.2 currents when NK1 receptors were activated differs from the previously reported inhibitory effect of D\textsubscript{1}-dopamine receptor activation on Ca\textsubscript{v}.3.2 channels expressed in the human adrenocarcinom cell line H295R, which was mediated selectively by G\textsubscript{\beta\gamma} subunits (Wolfe et al., 2003). This difference could be attributed to the low endogenous level of G\textsubscript{\beta\gamma}2 in HEK293 cells (Wolfe et al., 2003). Our data also show that inhibition of Ca\textsubscript{v}.3.2 channels by NK1 receptors is mediated by PLC\textbeta and PKC, because it was significantly diminished by their selective blockers U73122 and Bis I, respectively (Fig. 4). Furthermore, the inhibitory effect of NKA was totally occluded by the preceding application of the PKC activator PMA (Fig. 4, D–F). Overall, these results indicate that PKC could either act directly on Ca\textsubscript{v}.3.2 channel or via a regulatory protein (RP). The putative sites of action of dominant-negative G\textsubscript{\alpha} Q209L/D277L (G\textsubscript{\alpha}ND), RGS2, RGS3T, U73122, PMA, and Bis I are also indicated.

Fig. 5. Schematic summary of results of Ca\textsubscript{v}.3.2 channel inhibition by NK1 receptors. Solid arrows indicate the well established signaling pathways associated to NK1 receptors activation. Dashed arrows indicate the possibilities of signaling pathways related to PKC. PKC could either act directly on Ca\textsubscript{v}.3.2 channel or via a regulatory protein (RP). The putative sites of action of dominant-negative G\textsubscript{\alpha} Q209L/D277L (G\textsubscript{\alpha}ND), RGS2, RGS3T, U73122, PMA, and Bis I are also indicated.
T-type calcium channel modulation by G protein-coupled NK1 receptors and the molecular mechanisms underlying physiological relationships between CaV3.2 channels and novel information that may help in understanding the temperature-dependent effects of PMA. Likewise, PMA did not affect CaV3.2 channels when temperature was increased to 29°C (Schroeder et al., 1990). It is also interesting to note that experimental findings related to PKC-mediated modulation of T-type calcium channels in At20 cells when applied at room temperature, but triggered significantly stimulation when cells were maintained for 10 min at 37°C just before patch-clamp recording at room temperature (Chemin et al., 2007). These divergent results highlight the large variability among the experimental findings related to PKC-mediated modulation of T-type calcium channels. In future studies, it will be important to identify the specific isoforms of PKC or any other putative PKC-adaptors proteins (Churchill et al., 2009) activated by Gα11-coupled receptors, or PKA, under different experimental conditions (e.g., distinct expressing cell lines, channel isoform, and temperature) to attempt to understand the origins of this variability (Iftinca and Zamponi, 2009).

Although the physiological relevance of the inhibitory action of NK1 receptors on CaV3.2 channels remains to be established, it is possible to postulate its participation in physiological processes in which both native CaV3.2 channels and endogenous NK1 receptors are involved (i.e., neuronal rhythmogenesis and nociception). In this sense, it has been proposed that the attenuation of Ni2+-sensitive T-type currents by NK1 receptors in nucleus basalis cholinergic neurons may decrease the activation of CaV3.2-dependent K+ channels and thus maintain the neuronal excitability and prevent neuronal adaptation (Margeta-Mitrovic et al., 1997). In sensitive DRG neurons, it is also expected that NK1 receptors modulate T-type CaV3.2 channels because both proteins are endogenously expressed in these cells (Sculpatoreanu and de Groat, 2003; Iftinca et al., 2007). Unexpectedly, T-type currents in DRG neurons of adult rat were not affected by SP (Sculpatoreanu and de Groat, 2003). This quite surprising result is probably explained by the presence of unresponsive neurons to SP, given the significant heterogeneity of neuronal populations reported in DRG (Coste et al., 2007). In future studies, neuronal populations in DRG might be distinguished to better understand their electrophysiological characteristics and physiological function. Finally, the regulatory effect of NK1 receptors on T-type channels may also play a key role in neurotransmitter release (Bao et al., 1998), additional work is required to evaluate this issue.

In conclusion, we have shown that stimulation of NK1 receptors inhibited recombinant CaV3.2 channels through a voltage-independent mechanism that involved Gαq/11, phospholipase Cβ, and PKC signaling. Our data provide novel information that may help in understanding the physiological relationships between CaV3.2 channels and NK1 receptors and the molecular mechanisms underlying T-type calcium channel modulation by G protein-coupled receptors.

Acknowledgments

We thank Dr. Juan Carlos Gomez for kindly providing the CaV3.2 channel cDNA and Dr. Brett Adams for generously providing expression plasmids and helpful comments on the manuscript. We also thank Noelia Meza-Meza for reading the manuscript.
