ABSTRACT

Fluorometric Imaging Plate Reader (FLIPR®) membrane potential dye (FMP-Red-Dye) is a proprietary tool for basic discovery and high throughput drug screening for G-protein coupled receptors and ion channels. We optimized and validated this potentiometric probe to assay functional modulators of heterologous expressed GABA<sub>A</sub> receptor (GABA<sub>A</sub>R) isoforms (synaptic α1β3γ2, extrasynaptic α4β3δ, and β3 homopentomers). High-resolution mass spectrometry identified FMP-Red-dye as DisSBAC<sub>1</sub>(3). GABA<sub>A</sub>R expressing cells equilibrated with FMP-Red-Dye exhibited depolarized equilibrium membrane (E<sub>m</sub>) potentials compared to GABA<sub>A</sub>R-null cells. The channel blockers picrotoxin, fipronil, tetramethylenedisulfotetramine (TETS), and the competitive antagonist bicuculline reduced fluorescence near the levels in GABA<sub>A</sub>R-null cells indicating that FMR-Red-Dye, a barbiturate derivative, activates GABA<sub>A</sub>R-mediated outward Cl<sup>-</sup> current in the absence of GABA. GABA caused concentration-dependent increases in fluorescence with rank order of potencies among GABA<sub>A</sub>R isoforms consistent with results from voltage-clamp experiments (EC<sub>50</sub> values for α4β3δ, α1β3γ2, β3 homopentamers were 6 ± 1 nM, 40 ± 11 nM, >18 mM) respectively, whereas GABA<sub>A</sub>R-null cells were unresponsive. Neuroactive steroids (NAS) increased fluorescence of GABA<sub>A</sub>R expressing cells in the absence of GABA and demonstrated positive allosteric modulation (PAM) in the presence of GABA, whereas benzodiazepines only exhibited PAM activity. Of 20 NAS tested, allopregnanolone, (3α,5α,20E)-3-hydroxy-13,24-cyclo-18-norcholan-20-ene-21-carbonitrile (XJ-42), eltanolone, 5β-pregnan-3α,21-diol-20-one, and ganaxolone showed the highest potency. The FMP-Red-Dye-based assay described here provides a sensitive and quantitative method of assessing the activity of GABA<sub>A</sub>R agonists, antagonists and PAMs on diverse GABA<sub>A</sub>R isoforms. The assay has a wide range of applications, including screening for antiseizure agents and identifying channel blockers of interest to insecticide discovery or biosecurity.
INTRODUCTION

GABA\textsubscript{A} receptors (GABA\textsubscript{A}R) are ligand-gated anion channels that mediate inhibition in the mammalian central nervous system by responding to the neurotransmitter γ-aminobutyric acid (GABA) (Barnard et al., 1998). GABA\textsubscript{A}R dysfunctions are associated with epilepsy, autism, fragile X syndrome, depression and schizophrenia (Braat and Kooy, 2015; Rudolph and Möhler, 2014; Stafstrom et al., 2012; Verkman and Galietta, 2009). GABA\textsubscript{A}R are also the primary toxicological targets of several current use insecticides (e.g., fipronil) and pesticides of historical importance that persist in the environment (e.g., organochlorines) (Casida and Durkin, 2015). Importantly, GABA\textsubscript{A}R are a major pharmacological target for antiseizure drugs (Brodie et al., 2016).

GABA\textsubscript{A}R are pentameric anion channels composed of two α subunits, two β subunits and one subunit, which is designated γ, δ, ε, θ, or π. There are multiple isoforms of many of the subunits, six for α, three for β, and three for γ, allowing for a high degree of variation depending on brain region and developmental stage. Most synaptic GABA\textsubscript{A}R contain two α, two β subunits and one γ2 subunit, have a relatively low affinity for GABA and mediate fast phasic inhibition (Brickley and Mody, 2012; Rissman and Mobley, 2011). In contrast, extrasynaptic GABA\textsubscript{A}R often contain a δ subunit, have a higher affinity for GABA and mediate persistent tonic inhibition (Belelli et al., 2009; Bettler and Tiao, 2006; Brickley and Mody, 2012). In addition to the endogenous neurotransmitter, GABA, which binds to the interface of α and β subunits, GABA\textsubscript{A}R possess binding sites for neuroactive steroids (NAS), benzodiazepines, and barbiturates that allosterically enhance GABA-activated Cl\textsuperscript{−} conductance and in some instances activate Cl\textsuperscript{−} conductance in the absence of GABA, thereby exerting anxiolytic, sedative, and antiseizure effects that are useful for treating anxiety and sleep disorders, epilepsy, as well as...
serving as general anesthetics (Belelli et al., 2009; Belelli and Lambert, 2005; Herd et al., 2007). The benzodiazepine binding site is localized between the α and γ subunits, whereas NAS are known to have two binding sites, a potentiation site on the α subunit and a direct activator site in the α/β interface, both of which need to be occupied for potent channel activation (Akabas, 2004; Alvarez and Estrin, 2015; Campagna-Slater and Weaver, 2007; Hosie et al., 2007). Although the precise site(s) to which barbiturates bind remain elusive, domains within β subunit transmembrane segments TM2 and TM3 appear to be critical (Loscher and Rogawski, 2012). Interestingly, β3 subunits reconstitute a homopentameric channel that possesses NAS binding sites (Chen et al., 2012; Miller and Aricescu, 2014; Alvarez and Estrin, 2015).

Considering the utility of GABA_{A}R as therapeutic targets, there is substantial interest in the identification of improved GABA_{A}R modulators. A suitable high-throughput screening method would significantly aid in the identification of such agents. One potential method to assess GABA_{A}R function in a high-throughput manner uses the Fluorometric Imaging Plate Reader (FLIPR) membrane potential dye FMP-Red-Dye that redistributes across the plasma membrane in a voltage-dependent manner. Cell depolarization results in dye movement into the cell and binding to intracellular proteins and hydrophobic sites causing increased fluorescence signals and vice-versa occurs for hyperpolarization. Thus, FMP-Red-Dye allows monitoring of membrane potential changes in a bidirectional fashion independent of ion type. FMP-Red-Dye is convenient in that it does not require cells to be washed of excess dye after equilibration due to inclusion of a proprietary cell membrane impermeant red wavelength quencher, which results in a high signal-to-noise ratio (Fairless et al., 2013). Mennerick et al. reported that many voltage-sensitive dyes such as Di-4-ANEPPS and DiBAC_{4}(3) can directly activate and/or potentiate GABA_{A}R currents in a manner similar to NAS and barbiturates (Mennerick et al., 2010), questioning their usefulness for screening GABA_{A}R ligands. A previous study reported that
FMP-Red-Dye had a better performance than FMP-Blue-Dye, and that it produced results comparable to electrophysiology (Joesch et al., 2008). However, the chemical identity of FMP-Red-Dye is proprietary and the degree to which its constituents might influence GABA<sub>A</sub>R function and therefore limit the dye’s usefulness in characterizing GABA<sub>A</sub>R modulators has remained unclear.

Here we identify the voltage-sensitive component of FMP-Red-Dye as DiSBAC<sub>1</sub>(3), optimize and validate its use as a rapid throughput indicator of GABA<sub>A</sub>R activators, blockers and PAMs using FLIPR, and implement the assay to screen a small library of NAS and channel blockers. We show that FMP-Red-Dye can be used to differentiate GABA<sub>A</sub>R mediated responses in cell lines that stably or transiently express synaptic (α1β3γ2), extrasynaptic (α4β3δ), or β3 homomeric GABA<sub>A</sub>R isoforms. We conclude that the FMP-Red-Dye based assays provide sensitive and quantitative approaches to investigate functional drug effects on GABA<sub>A</sub>R isoforms, whether they are mediated by binding to the GABA recognition site, the NAS PAM sites, or convulsant channel blocking sites. The assay is useful for antiseizure drug screening and identifying novel channel blockers of interest to insecticide discovery or biosecurity.

**MATERIALS AND METHODS**

**Reagents**

Poly-L-lysine, cytosine arabinoside (Ara-C), picrotoxin (PTX), t-butylbicyclophosphorothionate (TBPS), fipronil, bicuculline, diazepam and γ-aminobutyric acid (GABA) were purchased from Sigma Aldrich (St. Louis, MO). Falcon™ 96-Well Imaging Plates with Lid were purchased from Fisher Scientific (Hampton, NH). FLIPR Membrane Potential Red Assay Kit (FMP-Red-Dye; Part number: R8123) was purchased from Molecular Devices Corporation (Sunnyvale, CA). Fluo4-AM was purchased from Life Technology (Hampton, NH).
GS21 supplement (Cat# GSM-3100) was purchased from MTI-Global stem (Gaithersburg, MD). Org 20599, alphaxalone, eltanolone, progesterone and midazolam were purchased from Tocris (Pittsburgh, PA). (3α,5α,20E)-3-hydroxy-13,24-cyclo-18-norcholan-20-ene-21-carbonitrile (XJ-42; Compound 63 in Covey and Jiang, 2014) was a generous gift of Dr. Douglas F. Covey (Washington University School of Medicine, St. Louis, MO), 3-[3α-hydroxy-3β-methyl-5α-androstan-17β-y1]-5-(hydroxymethyl)isoxazole (UCI-50027; Hogenkamp et al., 2014) was a generous gift of Dr. Kelvin W. Gee (University of California, Irvine, Irvine CA). Allopregnanolone was custom synthesized by SAFC Pharma (Madison, WI). Dehydroepiandrosterone sulfate, indiplon, and ursodeoxycholic acid (sodium salt) were purchased from Cayman Chemical (Ann Arbor, MI). Dehydroepiandrosterone acetate, dehydroepiandrosterone, cortisol, epiandrosterone, 20α-dihydropregnenolone, androstenediol, etiocholanolone, androsterone, alphadolone 21-acetate and tetrahydrocortexone were purchased from Steraloids (Newport, RI). Tetramethylenedisulfotetramine (TETS) was synthesized in the laboratory of Dr. Bruce Hammock as previously described (Zhao et al., 2014). All reagents were >97% purity.

**Heterologous Expression of GABA₄R Isoforms**

*Expression of GABA₄R subunits for potentiometric measurements with FLIPR FMP-Red-Dye*

Our goal was to develop a reliable, rapid throughput approach to quantitatively assess the influences of blockers, antagonists, and PAMs on the functional activity of diverse GABA₄R isoforms. To this end, we investigated cell lines that stably or transiently express three GABA₄R isoforms of different subunit compositions. A HEK 293 (human embryonic kidney) cell line that stably expresses human GABA₄R α1β3γ2 subunits (CYL3053 Precision hGABA-A α1/β3/γ2-HEK Recombinant Cell Line) was a generous gift of EMD Millipore Corporation, St. Charles,
MO. GABA\(_A\)R \(\alpha_1\beta_3\gamma_2\) heteropentomeric channels primarily localize to synaptic sites in mammalian neurons (McCartney et al., 2007). The GABA\(_A\)R-null HEK 293 line, which served as control, was purchased from American Type Culture Collection (ATCC-CRL-1573). Upon arrival both cell lines were expanded in Dulbecco’s modified Eagle’s medium/Ham’s F-12 (50/50 mix), 10% fetal bovine serum (FBS), 1% non-essential amino acid (Invitrogen, Carlsbad, CA) at 37°C in 5% CO\(_2\) and several bullets frozen to limit passage numbers. Cells expressing \(\alpha_1\beta_3\gamma_2\) subunits were kept under selection pressure with 400 µg/mL genticin, 100 µg/mL hygromycin B (Invitrogen) and 0.625 µg/ml puromycin (Clontech). GABA\(_A\)R null cells were cultured in 100 U/mL penicillin and 100 µg/mL streptomycin (Gibco) to minimize the risk of bacterial contamination. Cell lines were discarded after 15 passages. Cells were passaged when 70-80% confluent and harvested using 0.05% trypsin-EDTA and 50,000-60,000 cells/well (in a volume of 100 µl), seeded into poly-L-lysine-coated wells of a 96-well plate, and allowed to recover in the incubator overnight before FMP-Red-Dye loading and measurements of \(E_m\) with FLIPR.

A L-tk (mouse connective tissue) cell line expressing the human GABA\(_A\)R \(\alpha_4\beta_3\delta\) subunit combination under a dexamethasone inducible promoter was kindly provided by Dr. Trevor Smart (University College, London) (Brown et al., 2002). The \(\alpha_4\beta_3\delta\) subunit isoform is found at extrasynaptic sites in mammalian brain. The L-tk cell line was cultured in Dulbecco’s MEM plus glutamine, 4.5 g/L Na pyruvate and glucose with 10% FBS, in the presence of 1 mg/mL genticin and 0.2 mg/mL zeocin to select \(\alpha_4\beta_3\delta\) positive cells. Dexamethasone (1 µM; Invitrogen) or vehicle was added to the media to induce \(\alpha_4\beta_3\delta\) subunit expression or serve as GABA\(_A\)R-null cells, respectively, when 80-90% confluent. Cells were induced for 48 hrs, passaged using trypsin-EDTA 0.05%, and plated at 50,000-60,000 cells/well into 96 wells plates, and after 24 hrs recovery loaded with FMP-Red-Dye and membrane potential measured as described below.
Transient expression of GABA<sub>Α</sub>R β3 homopentamers in HEK 293 cells (ATCC CRL-1573) was achieved with a pcDNA3.1 expression vector generously provided by Dr. Robert L. Macdonald (Vanderbilt University, Nashville, TN). HEK 293 cells were cultured as described above. Twenty-four hours before transfection, cells were plated on 10-cm tissue culture treated dishes and transfected with plasmid DNA at 70%-90% confluence using TurboFect (Thermo Scientific) according to manufacturer’s instruction. At 24 hrs post-transfection, cells were dissociated with trypsin, counted and plated on poly-L-lysine coated 96-well plates (Falcon) at a density of 50,000-60,000 cells/well. All FLIPR experiments were carried out 48 hrs post transfection.

Expression of GABA<sub>Α</sub>R subunits for electrophysiological measurements

The human GABA<sub>Α</sub>R α<sub>1</sub>, β<sub>3</sub> and γ<sub>2</sub> cloned into pcDNA3.1 expression vectors were a gift from Dr. Robert L. Macdonald, Vanderbilt University, TN. Fibroblast L929 cells were cultured in Dulbecco's modified Eagle's medium (Lonza) supplemented with 10% fetal bovine serum, 100 U/mL penicillin and 100 mg/mL streptomycin (Invitrogen) and maintained in humidified 95% air and 5% CO<sub>2</sub> air at 37°C. Cells were transfected using FuGENE 6 (Roche) transfection reagent with an equal amount of each of the subunits in combination with pEGFP-C1. The transfection ratio of total cDNA to transfection reagent was 2:1 with equal amounts of α<sub>1</sub>, β<sub>3</sub>, γ<sub>2</sub> cDNA to reconstitute synaptic α<sub>1</sub>β<sub>3</sub>γ<sub>2</sub> GABA<sub>Α</sub>R, or β<sub>3</sub> alone to reconstitute homopentamers. Two days post-transfection, cells were plated on glass coverslips and transfected cells were identified using an epifluorescence microscope for electrophysiological measurements. Electrophysiological recordings from L-tk cells expressing GABA<sub>Α</sub>R α4β3δ subunit composition were obtained with culture and induction methods described above.
Rapid Throughput Analysis of GABA\textsubscript{A}R Modulators Using FLIPR FMP-Red-Dye

Once HEK 293 and L-tk cells were cultured on 96-well plates for 24 hrs, FMP-Red-Dye was reconstituted to 1× with 100 ml of Locke’s buffer (NaCl 154 mM, KCl 5.6 mM, CaCl\textsubscript{2} 2.3 mM, MgCl\textsubscript{2} 1 mM, HEPES 8.6 mM, glucose 5.6 mM, glycine 0.1 µM, pH 7.4) as recommended by the supplier (Molecular Devices). Growth media was removed from the wells and cells were loaded with 100 µl FMP-Red-Dye solution for 30 min in the dark at room temperature (except for experiments in Fig. 1 where fluorescence signals were recorded immediately). Each plate was transferred to the FLIPR Tetra Station and the dye excited at 510–545 nm, and the fluorescent signals recorded at 565–625 nm. Baseline recording were acquired for 2 min at a sampling rate of 1 Hz (400 ms of illumination per sample). FMP-Red-Dye is a slow-response potential-sensitive probe and the maximal response is usually seen within 2 min after triggering cellular depolarization or hyperpolarization (see Figures 3 and 4; (Dasheiff, 1985)). Cell responses were normalized by calculation $(F_{\text{max}} - F_{\text{min}})/F_{\text{min}} = \Delta F/F_0$, where $F_{\text{max}}$ was the maximum response in arbitrary fluorescence units (AFU), and $F_{\text{min}}$ was the baseline AFU value.

Although HEK 293 cells were unresponsive to vehicle additions, signals from L-tk cells expressing $\alpha_4\beta_3\delta$ subunits exhibited an abrupt but transient drop in fluorescence with addition of any solution, including Locke’s or vehicle, and therefore, all data from L-tk cells were normalized to vehicle baseline by subtraction.

Electrophysiological Recordings

Whole-cell voltage-clamp and current-clamp recordings were performed at room temperature with an EPC-10 HEKA amplifier. Cells were bathed in an external Ringer solution consisting of 160 mM NaCl, 4.5 mM KCl, 1 mM MgCl\textsubscript{2}, 2 mM CaCl\textsubscript{2}, 10 mM HEPES, pH 7.4, 311 mOsm. Recording electrodes were pulled and fire-polished to resistances of 1.8-2.4 M\Omega for voltage-clamp and 3-6 M\Omega for current-clamp experiments. Electrodes were filled with an
internal solution consisting of 154 mM KCl, 2 mM CaCl$_2$, 1 mM MgCl$_2$, 10 mM HEPES and 10 mM EGTA with pH 7.3 and 308 mOsm. Cells were voltage clamped at -80 mV and control currents were recorded under the application of 1 µM GABA, using a gravity-fed fast perfusion system, for 5 s followed by a 40-50 s wash with external solution. GABA concentration-response relationships were determined by testing increasing concentrations of GABA and normalizing GABA currents to the peak response induced by a saturating concentration of GABA. Normalized currents were fitted using the Hill equation to determine the EC$_{50}$ and EC$_{10}$ values. The EC$_{10}$ (1 µM) was used to evaluate the positive modulatory effects of the neurosteroids. The increases in Cl$^-$ current elicited in the presence of NAS were compared to the initial EC$_{10}$ to determine the fold increase in current. Test solutions of the NAS were freshly prepared immediately before each application onto cells. Membrane potential was recorded on the initial break into the cell while in current-clamp mode. For experiments involving FMP-Red-Dye, cells were pre-incubation with the dye for 30 min before recording in the absence or presence of fipronil. Cells were then exposed to 10 min of UV irradiation (460-490 nm) to induce the previously reported photodynamic effect of voltage-sensitive dyes (Mennerick et al., 2010).

**Data Analysis**

GraphPad Prism software (Version 6) was used for statistical analysis and graphing. EC$_{50}$ values were determined using nonlinear regression with a four-parameter logistic equation. Student’s $t$-test or F test (P<0.05) was applied to determine statistical differences. For post-hoc multiple comparison separate one-way ANOVA (for EC$_{50}$ and slope) using Tukey test was applied. Data are presented as the mean ± S.D. as stated. For electrophysiology, data analysis was performed using Excel (Microsoft) and Origin 7.0 (OriginLab Corp.) software. Data fitting
to the Hill equation to obtain EC_{50} values was performed with Origin 7.0. Data are presented as the mean ± S.D.

RESULTS

Optimization and Evaluation of FMP-Red-Dye Assay for Functional GABA_A R Screening

In initial experiments, HEK 293 cells stably expressing one of the widely expressed human synaptic GABA_A R isoforms α1β3γ2 or GABA_A R-null HEK 293 cells were used to test whether FMP-Red-Dye potentiates GABA_A R function in the absence of GABA as reported for other potentiometric dyes (Mennerick et al., 2010). FMP-Red-Dye signals were monitored in real-time within 1 min after dye addition to the cell medium. Initial fluorescence signals were similar for both GABA_A R-expressing and GABA_A R-null HEK 293 cells, but equilibrated to different steady-state fluorescence signals within 30 minutes, with α1β3γ2-expressing HEK 293 cells invariably achieving 2-fold higher steady-state fluorescence intensity than the respective null cells (Fig. 1A). Importantly, inclusion of PTX (1 μM) with dye addition prevented the rise in fluorescence in GABA_A R-expressing cells (Fig. 1A). In contrast, inclusion of GABA (1 μM) with the potentiometric dye caused an instantaneous increase in dye signal (within the 1 Hz resolution of the recording) followed by a more gradual equilibration of fluorescence to a 3-fold greater signal than that achieved in null cells by 30 min (Fig. 1C). GABA_A R-null cells showed a minimal time-dependent fluctuation in fluorescence and this response was unchanged by the presence of GABA. Similar results were obtained in studies comparing FMP-Red-Dye responses in L-tk cells expressing the extrasynaptic α4β3δ GABA_A R isoform with L-tk GABA_A R-null cells (Fig. 1B and 1D). These results indicate that by itself FMP-Red-Dye promotes slow depolarization of cells expressing either synaptic or extrasynaptic GABA_A R subunits but fails to cause this effect in the respective null cells. FMP-Red-Dye-induced cell depolarization was
prevented by PTX indicating that it requires functional GABA\(_A\) receptors. In contrast to the apparent slow activation of GABA\(_A\)R caused by FMP-Red-Dye, GABA induced a rapid activation of the receptors.

To further verify the accuracy of our interpretation, FMP-Red-Dye was equilibrated for 30 min with \(\alpha1\beta3\gamma2\)-expressing or GABA\(_A\)R-null HEK 293 cells and membrane potential recorded in the current clamp mode of the patch-clamp technique. While null HEK cells had a resting membrane potential of \(-78.6 \pm 6.3\) mV, which did not significantly change after incubation with FMP-Red-Dye (Fig. 2), \(\alpha1\beta3\gamma2\) expressing HEK 293 cells had a more positive resting membrane potential of \(-68.8 \pm 6.6\) mV \((P = 0.02)\), which was depolarized by a further 9 mV to \(-59.6 \pm 6.9\) mV \((P = 0.03)\) after incubation with FMP-Red-Dye for 30 min. This depolarization could be prevented by the GABA\(_A\)R blocker flupirinil (Fig. 2). Interestingly, 10 min of UV irradiation \((460-490\) nm) induced the previously reported photodynamic effect of voltage-sensitive dyes (Mennerick et al., 2010), and induced a further depolarization of the \(\alpha1\beta3\gamma2\) expressing HEK cells to \(-42.8 \pm 10.1\) mV \((P = 0.002)\) (Fig. 2).

The light-dependent influences of FMP-Red-Dye on cells expressing GABA\(_A\)R isoforms compelled us to determine its chemical identity, which to date has been proprietary information. The excitation and emission characteristics of the red dye \((\text{Ex} 470 / \text{Em} 580\) nm) suggest that the dye is a member of one of two structurally related families of voltage-sensitive dyes, DiBAC and/or DiSBAC. These dyes, which are derivatives of barbituric or thiobarbituric acid (Supplemental Fig. 1A), may bind at the barbiturate binding sites of GABA\(_A\)R (Mennerick et al., 2010). High-resolution mass spectrometry (HRMS) was used to elucidate the molecular identity of FMP-Red-Dye in its complex matrix. An experimental molecular mass of 379.0521 was obtained (Supplemental Fig. 1B), which is within 5 ppm of the theoretical molecular mass of
379.0534 of the voltage-sensitive dye 5,5'-(1-propen-1-yl-3-ylidene)bis[1,3-dimethyl-2-thio-barbituric acid (DiSBAC$_4$(3); CID 53485318).

Collectively these results, suggested that under tightly controlled experimental conditions the FMP-Red-Dye FLIPR platform could provide a sensitive and quantitative method for investigating pharmacological responses of GABA$_A$R isoforms to diverse direct GABA$_A$R activators, GABA$_A$R channel blockers of toxicological significance, and GABA$_A$R PAMs. To these ends, subsequent experiments were conducted following 30 min equilibration of cells seeded in 96-well plates with dye in the dark, followed by 2 min of baseline recording and 10 min of response recording after drug addition from a 96-well source plate. Excitation and emission were within visible wavelengths (ex 510–545 nm/em 565–625 nm) wells were excited by 400 ms duration pulsed illumination at a rate of 1 Hz. This protocol minimizes photodynamic influences of the FMP-Red-Dye, which may alter its activity on GABA$_A$R.

**Differential Potencies of GABA Toward Activating Synaptic and Extrasynaptic GABA$_A$R**

Concentration-response relationships for GABA were obtained using the FMP-Red-Dye assay in heterologous cells expressing either the synaptic GABA$_A$R isoform $\alpha_1\beta_3\gamma_2$ or the extrasynaptic isoform $\alpha_4\beta_3\delta$. Figure 3A shows representative responses to a range of GABA concentrations from 0.1 nM to 30 µM. The respective GABA$_A$R-null HEK 293 or L-tk cells, in contrast, did not respond to GABA. The concentration-response curves in Fig. 3B, left indicate that GABA was significantly more potent at eliciting a fluorescence signal in cells expressing $\alpha_4\beta_3\delta$ than in cells expressing $\alpha_1\beta_3\gamma_2$ (EC$_{50}$ values, 6 ± 1 nM, 95% CI: 4-16 nM and 40 ± 11 nM, 95% CI: 30-53 nM, respectively). HEK 293 cells expressing homopentameric $\beta_3$ subunits were largely insensitive to GABA at concentrations ≤1 mM, although these cells did exhibit
fluorescence responses to higher concentrations of GABA that were sensitive to PTX (see Fig. 5).

Voltage-clamp experiments performed with cells expressing the same subunit compositions used in the FMP-Red-Dye experiments confirmed that the cells expressing α4β3δ GABA_A R were more sensitive to GABA than those expressing α1β3γ2 subunits (P < 0.05; Fig. 3B, right). Comparing results using the two approaches indicated that the FMP-Red-Dye assay was a very sensitive measurement of GABA-triggered depolarization. Regardless, with both experimental approaches α4β3δ was more sensitive to GABA than α1β3γ2 (7-fold for FMP-Red-Dye assay and 12-fold for the patch-clamp technique).

Whether FMP-Red-Dye itself was directly responsible for the greater sensitivity to GABA obtained with the fluorescence assay than with the voltage-clamp assay was assessed by repeating the fluorescence experiments with a 2-fold dilution of dye in HEK 293 cells expressing α1β3γ2 (Fig. 3, inset). Under these conditions, the GABA concentration-effect relationship was shifted to the right such that the EC_{50} value (500 nM) was approximately 10-fold higher than with the FMP-Red-Dye dilutions recommended by the supplier (EC_{50}, 40 nM). These results suggest that FMP-Red-Dye acting as a PAM enhances the GABA sensitivity of the fluorescence assay. We found that the 2-fold dilution reduced signal-to-noise and dynamic range and that the assay became unreliable with 5-fold dilution. We therefore routinely used FMP-Red-Dye at the dilution recommended by the supplier.

Differential Potencies of Blockers in Cells Expressing Different GABA_A R Isoforms

PTX and TETS are seizure-triggering toxicants that inhibit GABA_A R Cl^{-} current by binding to overlapping sites within the ion conducting pore of the channel (Adelsberger et al., 1998; Cao et al., 2012; Olsen, 2006). We sought to demonstrate that the FMP-Red-Dye assay can
be used to assess the blocking activity of such agents in order to validate the assay as a means of identifying novel blockers and quantifying their activity in diverse GABA$_A$R isoforms. Both PTX and TETS reduced the FMP-Red-Dye signal in HEK 293 cells expressing the $\alpha$1$\beta$3$\gamma$2 subunit combination in a concentration-dependent manner, but had negligible influence on GABA$_A$R-null cells (Fig. 4; Table 1). TETS was slightly more potent than PTX (IC$_{50}$ values, 3.8 ± 1.1 µM and 6.5 ± 1.5 µM, respectively; P < 0.0001). Two additional allosteric blockers were tested, TBPS and the insecticide fipronil, and shown to have similar potencies to that of TETS (IC$_{50}$ values, 1.8 ± 1.2 and 2.6 ± 1.1 µM, respectively). The GABA$_A$R competitive antagonist bicuculline was approximately 20-times more potent than TBPS (IC$_{50}$ value, 0.1 ± 0.1 µM; P < 0.0001), although its efficacy at reducing fluorescence to that in GABA$_A$R-null cells was less complete at the highest concentration tested (10 µM, not shown).

L-tk cells expressing $\alpha$4$\beta$3$\delta$ subunits showed a distinct structure-activity relationship (SAR) with the blockers. Although the inhibitory potency of PTX was similar to that in cells expressing $\alpha$1$\beta$3$\gamma$2 (IC$_{50}$ values, 6.0 ± 1.0 µM vs. 6.5 ± 1.5 µM; P > 0.31), TETS was 2-fold less potent and TBPS and fipronil were nearly 200- and 10-fold more potent at the $\alpha$4$\beta$3$\delta$ isoform than at the $\alpha$1$\beta$3$\gamma$2 isoform (Table 1).

The divergent potencies exhibited by inhibitors towards cells expressing different GABA$_A$R isoforms compelled us to determine responses of cells expressing only the $\beta$3 subunit, which forms homopentamers that lack high-affinity GABA binding. HEK 293 cells expressing the $\beta$3 homomeric isoform exhibited substantially greater fluorescence than the respective GABA$_A$R-null cells (Fig. 5A) as was the case for the $\alpha$1$\beta$3$\gamma$2 isoform (Fig. 4), suggesting that FMP-Red-Dye is able to activate $\beta$3 homomeric GABA$_A$R as it does the other isoforms. PTX caused a concentration-dependent inhibition of fluorescence (Fig. 5C and D) that brought the fluorescence near that in GABA$_A$R-null cells. $\beta$3-expressing cells failed to response to GABA at
concentrations below 1 mM (Fig. 5B), but as in previous voltage-clamp studies (Wooltorton et al., 1997) they did appear to be activated by high (>10 mM) GABA concentrations. Figure 6A showed that hyperpolarization produced by fipronil was also concentration dependent with fipronil being approximately 10- and 50-fold more potent at restoring \( E_m \) to levels near those measured with GABA\(_A\)-null HEK 293 cells than PTX or TETS (Table 1).

**Detection of Direct Activation and PAM Activity in GABA\(_A\)R Isoforms**

Neuroactive steroids (NAS) have been shown to have GABA\(_A\)R PAM activity at low concentrations and to directly activate GABA\(_A\)R at higher concentrations (Belelli and Lambert, 2005; Wang, 2011). Twenty NAS and related structures were tested for activity on GABA\(_A\)R in the FMP-Red-Dye assay with heterologous cells expressing \( \alpha_1\beta_3\gamma_2 \), \( \alpha_4\beta_3\delta \) or \( \beta_3 \) homomeric isoforms, and the potency and efficacy of active compounds quantified (Figs. 7 and 8; Table 2). Several NAS caused concentration-dependent increases in fluorescence in cells expressing the \( \alpha_1\beta_3\gamma_2 \) and \( \alpha_4\beta_3\delta \) isoforms with EC\(_{50}\) values below 1 \( \mu \)M whereas the respective GABA\(_A\)R-null cells failed to respond to any NAS. The rank order of potencies (based on EC\(_{50}\) values) in cells expressing the \( \alpha_1\beta_3\gamma_2 \) isoform was: allopregnanolone \( \sim \) eltanolone \( \sim \) XJ-42 \( > \) ganaxolone \( \sim \) 5\( \beta,3\alpha \)-THDOC \( > \) alphaxalone > alphadolone 21-acetate \( > \) androstosterone. Of these, 5\( \beta,3\alpha \)-THDOC and alphadolone 21-acetate showed significantly (\( P < 0.001 \)) lower efficacy (maximum \( \Delta F/F_0 \)) than the other active NAS (Table 2). By contrast, cells expressing the \( \alpha_4\beta_3\delta \) isoform showed a different rank order of potencies: eltanolone \( > \) allopregnanolone \( > \) ganaxolone \( \sim \) 5\( \beta,3\alpha \)-THDOC \( \sim \) XJ-42 \( \sim \) alphaxalone \( > \) alphadolone 21-acetate \( > \) androstosterone. XJ-42 exhibited significantly greater maximal efficacy in cells expressing \( \alpha_4\beta_3\delta \) (\( P < 0.007 \)) than the other active NAS whereas 5\( \beta,3\alpha \)-THDOC had significantly lower efficacy (Fig 7E and 8E; Table 2). Overall, with the exception of eltanolone, all active NAS were modestly more potent
on α1β3γ2 than α4β3δ (P < 0.0038). In contrast to other isoforms, β3 homopentameric channels were insensitive to allopregnanolone (Fig. 6B) and in general to all NAS tested (not shown).

We next tested whether the FMP-Red-Dye assay is able to detect the PAM activity of NAS and exposed cells to a low, submaximal concentration of GABA (10 nM) without and with various concentrations of NAS. Fig. 9A plots the fold increase in fluorescence signal in HEK 293 cells expressing the α1β3γ2 isoform in the presence of allopregnanolone or ganaxolone compared to the signal elicited by GABA alone. The EC$_{50}$ values for the two NAS are 1.7 ± 1.2 nM ($n_H = 1.49$) and 20 ± 13 nM ($n_H = 1.43$), respectively. Because GABA$_A$R channel open probability increases and maximizes with increasing GABA concentrations, the relative increase in response by a PAM will necessarily drop in magnitude as the GABA concentration is increased. This is demonstrated in the experiment of Fig. S3. The relative enhancement produced by 1 nM allopregnanolone in the presence of 1, 10, and 100 nM GABA is greatest at the lowest GABA concentration, reduced at 10 nM GABA, and there is no further enhancement with 100 nM GABA, which is a near saturating GABA concentration in the FMP-Red-Dye assay (Fig. 3B). Results from voltage-clamp experiments demonstrating the PAM effect with transiently expressed α1β3γ2 GABA$_A$R are shown in Fig. 9B. Addition of allopregnanolone or ganaxolone in the presence of the GABA EC$_{10}$ values (1 µM, Fig. 3B) caused a concentration-dependent enhancement of the Cl$^-$ current with EC$_{50}$ values of 71.7 ± 14.2 nM ($n_H = 1.8$) and 114.8 ± 15.6 nM ($n_H = 2.2$), respectively.

Finally, we tested whether the FMP-Red-Dye assay could detect direct or PAM effects of the benzodiazepine midazolam (MDZ). In the absence of GABA, midazolam failed to substantially enhance the fluorescence signal in HEK 293 cells expressing the α1β3γ2 isoform at concentrations ≤1 µM although at higher concentrations a small signal was elicited (Fig. 10).
the presence of suboptimal GABA (10 nM), midazolam caused a concentration-dependent increase in fluorescence signal with EC$_{50}$ value of 51 ± 12 nM (Fig. 10).

**DISCUSSION**

The present results demonstrate that FMP-Red-Dye, which contains the fluorescent voltage-sensor DiSBAC$_{1}(3)$, can be used with the FLIPR platform to characterize a wide range of GABA$_A$R blockers and modulators in heterologously expressed recombinant GABA$_A$R. However, because FMP-Red-Dye interacts with GABA$_A$R, causing a PAM effect, quantitative results obtained with the potentiometric dye approach may not correspond to results obtained with other methods, such as the gold standard voltage-clamp technique. The potentiometric indicator DiSBAC$_{1}(3)$ is a thio-barbiturate. Compared to other potentiometric dyes in the family of oxonol slow indicators, DiSBAC indicators have been reported to have reduced direct activating and PAM influences on GABA$_A$R compared to BiBAC dyes (Mennerick et al., 2010). Our present data indicate that DiSBAC$_{1}(3)$ is a relatively weak direct activator of GABA$_A$R-mediated Cl$^-$ currents in the absence of GABA or UV irradiation, but as previously reported for oxonols, UV irradiation greatly potentiates this activity. Equilibration of HEK 293 or L-tk cells that express GABA$_A$R with FMP-Red-dye in the dark results in a modest chronic depolarization of resting $E_m$ regardless of GABA$_A$R isoform expression compared to respective GABA$_A$R-null cells. Depolarization of cells expressing GABA$_A$R by FMP-Red-dye is likely the direct consequence of interactions of the dye molecules at barbiturate sites localized within membrane spanning regions of the β subunit to directly activate Cl$^-$ current (Löschler and Rogawski, 2012). In the case of our HEK 293 or L-tk cell expression models, the electrochemical gradient for chloride causes an inward current (outward Cl$^-$ flux) that results in depolarization when GABA$_A$R channel opening is increased and hyperpolarization when channel opening is decreased, consistent with voltage-clamp measurements here and those of others in such cell types. This interpretation is supported by the experimental findings with channel blockers,
including PTX, TETS or fipronil, that bring the fluorescence signal back to levels near those measured in the respective GABA-A-R-null cells.

It is noteworthy that in both the potentiometric and voltage-clamp assays, GABA was ~10-fold more potent as an activator of the extrasynaptic subunit combination α4β3δ than of the synaptic subunit combination α1β3γ2, while β3 homopentamers were insensitive to GABA (≤1 mM). These differences in GABA sensitivity are in accord with previous reports (Brickley and Mody, 2012; Mortensen et al., 2011). For both the synaptic and extrasynaptic subunit combinations, GABA potency in the FMP-Red-Dye assay was two orders of magnitude greater than in patch-clamp experiments. A review of the available electrophysiological literature indicates that conventional barbiturates, such as pentobarbital, induce a more modest 3- to 10-fold leftward shift in sensitivity to GABA (Lösch and Rogawski, 2012; Steinbach and Akk, 2001). The basis for the extreme GABA sensitivity in the FMP-Red-Dye assay is not fully understood but could relate to the fact that the DiSBAC1(3) molecule contains two thiobarbiturate moieties, which could interact with multiple sites on GABA-A receptors thus acting as synergistic positive modulators. Whatever the cause of the high sensitivity to GABA, the FMP-Red-Dye FLIPR platform provides an extremely sensitive assay for detecting and quantifying responses to GABA-A-R agonists, antagonists and modulators on defined GABA-A-R subtypes.

Two new findings emerge from studies with the potentiometric assay. First, the rank order of potencies of noncompetitive GABA-A-R blockers towards α1β3γ2 (TBPS>TETS>fipronil>PTX) differs from that of α4β3δ (TBPS>>fipronil>>TETS~PTX). Second, the approximately 10- and 100-fold higher potencies of fipronil and TBPS towards blocking the basal activity (i.e., normalizing \( E_m \) in the absence of GABA) of cells expressing the extrasynaptic α4β3δ combination compared to either those that express the synaptic α1β3γ2 combination or β3 homopentamers is particularly noteworthy in that it suggests for the first time that blockers with both compact and elongated chemical structures (Zhao et al.,
2014) selectively target major extrasynaptic GABA_A R within the mammalian central nervous system, albeit with TBPS having 25-fold higher potency than fipronil (see Table 1). We also note that fipronil is substantially more potent than either PTX or TETS (10-fold and 50-fold, respectively) towards β3 homopentamers, as previously demonstrated in receptor binding studies (Chen et al., 2006; Zhao et al., 2014). The findings identifying differential potencies of blockers towards synaptic and extrasynaptic GABA_A R subunit combinations could help explain outstanding questions with respect to toxicological mechanisms, including the pharmacodynamic basis for the different seizure-inducing potencies of different GABA_A R blockers. In addition, if it is the case that TBPS and fipronil are generally more active at extrasynaptic GABA_A R subunit combinations, these agents may be useful as pharmacological tools for selectively blocking these receptors. The competitive GABA_A R antagonist bicuculline was the most potent blocker of the α1β3γ2 isoform that we studied. However, it failed to completely reduce the fluorescence to that in GABA_A R-null cells, a result fully in accord with previous voltage-clamp studies where high concentrations of bicuculline fully block GABA activated Cl− current but not barbiturate-activated current (Rho et al., 1996). Interestingly, bicuculline exhibited the opposite relative selectivity to that of TBPS and fipronil inasmuch as the α4β3δ isoform was less sensitive than the α1β3γ2 isoform.

The FMP-Red-Dye potentiometric assay proved to be an excellent system for characterizing both the directly activating and the PAM effects of NAS. Of 20 NAS tested, only 8 activated GABA_A R with potencies (EC_{50} values) below 1 μM (Table 2). In general, the SAR that emerges from the FMP-Red-Dye assay is consistent with previous reports in the literature (Kokate et al., 1994; Akk et al., 2007; Borowicz et al., 2011; Wang, 2011; Reddy and Rogawski, 2012). Both synaptic and extrasynaptic GABA_A R subtypes respond to NAS (Bianchi and Macdonald, 2003; Maksay et al., 2000). In general, we found comparable potencies (EC_{50} values) and efficacies (∆F/F_0 values) of the active steroids at the synaptic α1β3γ2 isoform and
the extrasynaptic α4β3δ isoform. In contrast to the other active steroids which all had similar maximal efficacies, XJ-42, a pentacyclic analog of allopregnanolone with a 17,18-fused carbonitrile-substituted 6-member carbocyclic ring, had substantially greater efficacy although its potency was in line with that of the other active steroids. This observation indicates that modifications that replace the 17-acetyl group of allopregnanolone can enhance neuroactive steroid efficacy, which may provide therapeutic advantages. In addition to directly activating GABA_A, at low concentrations, NAS act as PAMs to enhance the action of GABA (Kokate et al., 1994). The FMP-Red-Dye assay is able to demonstrate such an effect as illustrated in Fig. 9A, which compares the PAM activity of allopregnanolone and ganaxolone, two exemplary NAS currently under clinical investigation (Reddy and Rogawski, 2012). In experiments with the synaptic α1β3γ2 combination, both steroids exhibit substantial PAM activity in the FMP-Red-Dye assay, with allopregnanolone demonstrating modestly greater potency than ganaxolone. Similar relative potencies are obtained in patch-clamp recordings (Fig. 9B; see also, Carter et al., 1997). Because of the heightened sensitivity to GABA due to the influence of FMP-Red-Dye, the PAM activity of NAS was measured in the presence of a low concentration GABA (10 nM), to prevent saturation evident even at 100 nM GABA (Supplemental Fig. 3). Under these conditions, the FMP-Red-Dye assay generates EC_50 and fold-increase values that indicate substantially greater potency and efficacy than obtained with electrophysiological methods, but the relative potencies are consistent with previous reports using receptor binding and electrophysiological methods (Carter et al., 1997).

Conclusion

FMP-Red-Dye based assays provide sensitive and quantitative approaches to investigate functional interactions with GABA_A subtypes mediated through the GABA site, PAM sites, or
channel pore sites, and is useful not only for discovery of antiseizure drugs, but also for identifying novel channel blockers of interest to insecticide discovery or biosecurity.

FIGURE LEGENDS

Figure 1. FMP-Red-Dye modulates α1β3γ2 and α4β3δ GABA_A receptors expressed in HEK 293 and L-tk cells, respectively. (A, B) FMP-Red-Dye causes a slow increase in fluorescence (AFU) in cells expressing both receptor types over a 30 min period that is blocked by 1 µM PTX. AFU in GABA_A-R-null cells minimally changes during the 30 min after onset of FMP-Red-Dye exposure. (C, D) 1 µM GABA cases an instantaneous increase in AFU in cells expressing both receptors types compared to GABA_A-R-null cells; AFU continues to slowly rise over 30 min. GABA has no effect on AFU in GABA_A-R-null cells.

Figure 2. Current clamp experiments demonstrating that incubation with FMP-Red-Dye leads to a depolarization of GABA_AR expressing cells. Membrane potential (V_m) values of α1β3γ2 expressing HEK 293 cells and GABA_A-R-null HEK 293 cells measured by current clamp under three conditions: 1) no treatment; 2) incubation with FMP-Red-Dye for 30 min prior to recording membrane potential in the absence or presence of 50 µM fipronil (FIP); 3) incubation with FMP-Red-Dye for 30 min followed by 10 min of UV irradiation prior to recording membrane potential. n = 8-10 cells per condition. Unpaired t-test was used to compare the treatments with control (white bar). * = P < 0.05, ** = P < 0.01. Each bar represents mean ± S.D.

Figure 3. Comparison of GABA responses in cells expressing GABA_AR as assessed with the FMP-Red-Dye technique and by voltage-clamp recording. (A) Both α1β3γ2 and α4β3δ GABA_AR expressing cells exhibit fluorescence responses of increasing amplitude following exposure to increasing concentrations of GABA in the range 0.1 nM to 30 µM. In these experiments, cells were equilibrated with FMP-Red-Dye for 30 min. Then, baseline fluorescence was recorded for 2 min followed by exposure to vehicle (VEH; 0.01% DMSO) or GABA. ΔF/F₀ values were determined at the peak of the fluorescence response. The black arrow indicates the time of GABA addition; GABA remained for the duration of the recording. GABA_A-R-null cells do not respond to GABA. (B, left) Concentration-response curves for GABA based on fluorescence responses reveals that α4β3δ GABA_AR expressed in L-tk cells are significantly more sensitive to GABA than α1β3γ2 GABA_AR expressed in HEK 293 cells [EC₅₀ values, 6 nM (95% CI: 4-8 nM) (n_H = 0.7; n=10) and 40 nM (95% CI: 33-54 nM) (n_H = 1.1; n=10). β3 homopentamers transiently expressed in HEK 293 cell are largely insensitive to GABA (EC₅₀ >1 mM). Dose-response curves were plotted using nonlinear regression with a four-parameter logistic equation and independent F test was applied to determine the statistical differences for EC₅₀ values and slopes between α1β3γ2 and α4β3δ GABAAR expressing cell lines. Each data point represents mean ± S.D. of data from
10 wells. (B, right) Concentration-response curves for GABA activation of α1β2γ2 receptors in HEK 293 cells and α4β3δ receptors in L-tk cells from whole-cell voltage-clamp recordings [EC₅₀ values are 6.67 μM (95% CI: 5.30-8.04 μM, nₓ = 1.8; n=13) and 549 (95% CI: 435-663 nM, nᵧ = 1.8; n=10) *. Each data point represents mean ± S.D. P < 0.0001 for α1β3γ2 versus α4β3δ].

Figure 4. Picrotoxin (PTX) and TETS block α₁β₂γ₂ GABA₄-R-dependent FMP-Red-Dye fluorescence. HEK 293 cells stably transfected with α1β3γ2 GABA₄-R were exposed to FMP-Red-Dye for 30 min to activate the receptors. GABA₄-R-null cells were used as control. PTX (A) or TETS (C) caused a slow, concentration-dependent inhibition of the fluorescence in cells expressing α1β3γ2 GABA₄-R; minimal effects were obtained in GABA₄-R-null cells. Arrows indicate time of addition of PTX and TETS to the wells; the blockers were not removed. (B, D) Plots of ΔF/F₀ from experiments similar to those illustrated in (A, C). Each plot represents 8 experiments. IC₅₀ values are 6.5 μM (95% CI: 3.2-12 μM) and 3.8 μM (95% CI: 2.8-5.2 μM) for PTX and TETS, respectively. TETS is significantly more potent than PTX (P < 0.0001). Dose-response curves were plotted using nonlinear regression with a four-parameter logistic equation and independent F test was applied to determine the statistical differences for EC₅₀ values between TETS and PTX. Each data point represents mean ± S.D. of data from 8 wells. Red traces represent responses to vehicle (0.01% DMSO). * P < 0.0001.

Figure 5. GABA potentiation and PTX inhibition of β₃ homopentameric GABA₄-R-dependent FMP-Red-Dye fluorescence. HEK 293 cells transiently transfected with β3 homopentameric GABA₄-R were exposed to FMP-Red-Dye for 30 min to activate the receptors. GABA₄-R-null cells were used as control. (A) GABA caused a slow, concentration-dependent potentiation of the fluorescence in cells expressing β3 homopentameric GABA₄-R; minimal effects were obtained in GABA₄-R-null cells. (B) PTX caused a slow, concentration-dependent inhibition of the fluorescence in cells expressing β3 homopentameric GABA₄-R; minimal effects were obtained in GABA₄-R-null cells. Arrows indicate time of addition of GABA and PTX, which was not removed. Red traces represents the responses to vehicle (0.01% DMSO). (B, D) Plots of ΔF/F₀ from experiments similar to those illustrated in (A, C). Each data point represents mean ± S.D. of data from 10 wells. EC₅₀ value for GABA could not be determined as the response did not plateau. IC₅₀ value for PTX is 1.8 μM (95% CI: 1.4-2.2 μM). Dose-response curves were plotted for PTX using nonlinear regression with a four-parameter logistic equation.

Figure 6. Fipronil blocks β3-homomeric GABA₄ receptors, while allpregnandalone fails to affect the fluorescence signal even at concentrations≥10 μM. (A) Fipronil blocks β3 receptors in a concentration-dependent manner, but does not have any significant effects on GABA₄-R-null cells. Dose-response curves were plotted using nonlinear regression with a four-parameter logistic equation. Each data point
represents mean ± S.D. of data from 8 wells. (B) Allopregnanolone, does not have any effect even at 10 µM.

**Figure 7. Neuroactive steroid-induced FMP-Red-Dye fluorescence responses of α1β3γ2 GABA<sub>A</sub>R in HEK 293 cells.** (A, B, C & D) Representative traces of responses to 0.01 nM to 10 µM of eltanolone, allopregnanolone, XJ-42 and ganaxolone, respectively. Arrow indicates time of addition of the test compound, which was not removed. Red traces represent the responses to vehicle (0.01% DMSO). (E) Concentration-response curves for each of the neuroactive steroids and cortisol. Dose-response curves were plotted using nonlinear regression with a four-parameter logistic equation. Separate one way anova with additional correction (Tukey) for post-hoc multiple comparison was applied for EC<sub>50</sub> and slope to determine the statistical differences within a subunit composition –not across subtypes (Table 2). Each data point represents mean ± S.D. of data from 10 wells.* P value <0.0001

**Figure 8. Neuroactive steroid-induced FMP-Red-Dye fluorescence responses of α4β3δ GABA<sub>A</sub> receptors in L-tk cells.** (A, B, C & D) Representative traces of responses to 0.01 nM to 10 µM of eltanolone, allopregnanolone, XJ-42 and ganaxolone, respectively. Arrow indicates time of addition of test compound, which was not removed. Red traces represent the responses to vehicle (0.01% DMSO). (E) Concentration-response curves for each of the neuroactive steroids. Dose-response curves were plotted using nonlinear regression with a four-parameter logistic equation. Separate one way anova with additional correction (Tukey) for post-hoc multiple comparison was applied for EC<sub>50</sub> and slope to determine the statistical differences within a subunit composition –not across subtypes (Table 2). Each data point represents mean ± S.D. of data from 10 wells.* P value <0.0001

**Figure 9. Allopregnanolone and ganaxolone potentiation of GABA responses of α1β3γ2 GABA<sub>A</sub>R in HEK 293 cells.** (A) Concentration-response curves for allopregnanolone and ganaxolone potentiation of FMP-red dye responses to 10 nM GABA. The graph plots mean ± S.D. fold increase in peak response in the presence the neuroactive steroid compared with the response to 10 nM GABA alone. Each data point is the mean ± S.D. of measurements of 10 wells. EC<sub>50</sub> values for allopregnanolone and ganaxolone are 1.7 nM (95% CI: 1.3-3.1 nM, n<sub>f</sub> = 1.5) and 20 nM (95% CI: 14-55 nM, n<sub>f</sub> = 1.4), respectively (P < 0.0001). Dose-response curves were plotted using nonlinear regression with a four-parameter logistic equation and independent F test was applied to determine the statistical differences for EC<sub>50</sub> values and slopes between allopregnanolone and ganaxolone in combination with 10 nM GABA in α1β3γ2 GABA<sub>A</sub>R in HEK 293 cells. Inset shows representative traces with addition of GABA alone and GABA plus allopregnanolone at concentrations of 1 nM and 10 nM. (B) Concentration-response curves for allopregnanolone and ganaxolone potentiation of peak inward Cl<sup>-</sup> current responses to 1 µM GABA (EC<sub>10</sub> value) in patch-
clamp recordings. Each data point is the mean ± S.D. of measurements of 3-6 cells. EC\textsubscript{50} values for allopregnanolone and ganaxolone are 71.3 nM (95% CI: 57.1-85.5 nM, \textit{n} = 1.8) and 114.8 nM (95% CI: 99.2-130.4 nM, \textit{n} = 2.2). Inset shows representative traces with application of GABA alone and GABA plus allopregnanolone at 100 nM and 175 nM.

**Figure 10. Effects of midazolam on FMP-Red-Dye fluorescence in cells expressing \(a1\beta3\gamma2\) GABA\textsubscript{A}R.** In the absence of GABA, midazolam fails to generate substantial fluorescence signals compared with vehicle (VEH) except at high concentrations (>1 µM). GABA (10 nM) induces a small fluorescence signal. Combination of midazolam and GABA results in potentiation of the signal [EC\textsubscript{50}, 51 nM (95% CI: 30-83 nM)]. Dose-response curves were plotted using nonlinear regression with a four-parameter logistic equation. Each data point represents the mean ± S.D. of measurements in 8 cells.

Dose-response curves were plotted using nonlinear regression with a four-parameter logistic equation. Separate one way ANOVA with additional correction (Tukey) for post-hoc multiple comparison was applied for EC<sub>50</sub> and slope to determine the statistical differences among them. IC<sub>50</sub> values and slopes were compared within each receptor isoform. On α1β3γ2 GABA<sub>A</sub> receptors bicuculline is significantly more potent than the other blockers; the IC<sub>50</sub> values of the other blockers were not significantly different from each other. On α4β3δ GABA<sub>A</sub> receptors, TBPS and fipronil are significantly more potent than the other blockers. The slope values for PTX and TETS are significantly smaller than for the other blockers. On β3 homopentamer, fipronil is more potent than PTX and TETS. The slope for fipronil is significantly smaller than that of PTX and TETS. Each data point represents the mean (with 95% confidence interval in parenthesis) of measurements in 8 wells. * P value <0.001 when comparing IC<sub>50</sub> values or slopes of blockers within each receptor isoform.

</tbody>
</table>
In Table 2, dose-response curves were fit by nonlinear regression with a four-parameter logistic equation. Statistical differences among EC\textsubscript{50} and maximum ΔF/F\textsubscript{0} values were assessed independently by one-way ANOVA with post-hoc pairwise comparisons using Tukey’s HSD test. On α1β3γ2 GABAA receptors eltanolone with IC\textsubscript{50} value of 8 nM and maximum of 0.17 is the most potent and efficacious compound. Although on α4β3δ GABAA receptors eltanolone with IC\textsubscript{50} value of 6 nM is the most potent compound, XJ-42 with maximum of 0.41 is the most efficacious compound. Each data point represents the mean (with 95% confidence interval in parenthesis) of measurements in 10 wells. * P value <0.001 when comparing IC\textsubscript{50} values or maximum of compounds within each receptor isoform.
