ABSTRACT
The tetrapeptide Arg-Leu-Tyr-Glu (RLYE), a vascular endothelial growth factor (VEGF) receptor-2 antagonist, has been used previously either alone or in combination with chemotherapeutic drugs for treating colorectal cancer in a mouse model. We analyzed the half-life of the peptide and found that because of degradation by aminopeptidases B and N, it had a short half-life of 1.2 hours in the serum. Therefore, to increase the stability and potency of the peptide, we designed the modified peptide, N-terminally acetylated RLYE (Ac-RLYE), which had a strongly stabilized half-life of 8.8 hours in serum compared with the original parent peptide. The IC₅₀ value of Ac-RLYE for VEGF-A-induced endothelial cell migration decreased to approximately 37.1 pm from 89.1 pm for the parent peptide. Using a mouse xenograft tumor model, we demonstrated that Ac-RLYE was more potent than RLYE in inhibiting tumor angiogenesis and growth, improving vascular integrity and normalization through enhanced endothelial cell junctions and pericyte coverage of the tumor vasculature, and impeding the infiltration of macrophages into tumor and their polarization to the M2 phenotype. Furthermore, combined treatment of Ac-RLYE with the chemotherapeutic drug, irinotecan, exhibited synergistic effects on M1-like macrophage activation and apoptosis and growth inhibition of tumor cells. These findings provide evidence that the N-terminal acetylation augments the therapeutic effect of RLYE in solid tumors via inhibition of tumor angiogenesis, improvement of tumor vessel integrity and normalization, and enhancement of the livery and efficacy of the coadministered chemotherapeutic drugs.

SIGNIFICANCE STATEMENT
The results of this study demonstrate that the N-terminal acetylation of the tetrapeptide RLYE (Ac-RLYE), a novel vascular endothelial growth factor receptor-2 (VEGFR-2) inhibitor, significantly improves its serum stability, antiangiogenic activity, and vascular normalizing potency, resulting in enhanced therapeutic effect on solid tumors. Furthermore, the combined treatment of Ac-RLYE with the chemotherapeutic drug, irinotecan, synergistically enhanced its antitumor efficacy by improving the perfusion and delivery of the drug into the tumors and stimulating the conversion of the tumor-associated macrophages to an immunostimulatory M1-like antitumor phenotype.

Introduction
Tumor angiogenesis improves the formation of blood vessels for supplying oxygen, nutrients, and growth factors required for the growth and survival of tumors (Folkman, 2007). This process is initiated from pre-existing vasculature around the tumors (Papetti and Herman, 2002; Folkman, 2007). Angiogenesis is precisely regulated by a balance between the proangiogenic and antiangiogenic factors. Among the various angiogenic factors, vascular endothelial growth factor (VEGF), which is predominantly induced under hypoxic conditions, including robust tumor growth, is identified as the most potent and prominent factor to induce physiologic and pathologic...
neovascularization through the activation of endothelial cells (Papetti and Herman, 2002). Thus, VEGF contributes to tumor progression by promoting angiogenesis (Folkman, 2007).

The VEGF family includes five VEGF isoforms (VEGF-A, VEGF-B, VEGF-C, VEGF-D, and VEGF-E) and placental growth factor (Hicklin and Ellis, 2005). Of these, VEGF-A is the most potent inducer of angiogenesis. All the VEGF isoforms bind to the receptor tyrosine kinases, VEGF receptor-1 (VEGFR-1), VEGFR-2, and VEGFR-3; however, VEGF-A binds to and activates both VEGFR-1 and VEGFR-2, which are expressed mainly in endothelial cells. VEGFR-1 has a higher binding affinity for VEGF-A compared with VEGFR-2, whereas its angiogenic activity is much weaker than that of VEGFR-2 (Sawano et al., 1996). Therefore, the VEGF-A/VEGFR-2 pathway is the main axis driving angiogenesis under physiologic and pathologic conditions.

Numerous studies have demonstrated that antibodies and chemical drugs targeting the VEGF-A/VEGFR-2 axis are potential strategies to inhibit tumor angiogenesis, thus abrogating tumor progression and metastasis. Although some of these drugs, such as bevacizumab, ramucirumab, sunitinib, and axitinib, have been clinically used to treat several solid tumors (McIntyre and Harris, 2015), they have some limitations because of unwanted adverse effects (Kamba and McDonald, 2007; Verheul and Pinedo, 2007; Cook and Figg, 2010; Taugourdeau-Raymond et al., 2012). For example, the anti-VEGF-A antibody bevacizumab frequently induces serious side effects, including severe hypertension, thromboembolic events, bleeding, and hemorrhage in cancer patients (Kamba and McDonald, 2007; Taugourdeau-Raymond et al., 2012). In addition, chemical drugs that inhibit VEGF receptor tyrosine kinase can inhibit several other tyrosine kinases owing to their low specificity and can also lead to drug-resistance, hypertension, and proteinuria (Verheul and Pinedo, 2007; Cook and Figg, 2010); however, the anti-VEGFR-2 antibody ramucirumab is predicted to be a promising drug for treating cancer patients since it inhibits tumor angiogenesis without significant adverse effects (Fuchs et al., 2014; Javle et al., 2014), suggesting that VEGFR-2 could be a potential target for tumor therapy.

We had previously developed the antiangiogenic tetrapeptide Arg-Leu-Tyr-Glu (RLYE) from the amino acid sequence of Lys-Leu-Tyr-Asp (KLYD) present in the antiangiogenic kringle domain 5 of plasminogen (Sheppard et al., 2004; Baek et al., 2015). RLYE inhibited VEGF-induced angiogenesis in vitro more effectively than KLYD (Baek et al., 2015). Further studies demonstrated that RLYE acts as a VEGFR-2 antagonist and inhibits tumor angiogenesis by binding to VEGFR-2 at the same binding site as VEGF-A (Baek et al., 2015, 2017). Here, we found that RLYE had a short half-life in serum; therefore, we developed a more stable peptide, Ac-RLYE, by N-terminal acetylation of RLYE. The modified peptide potentially inhibited tumor angiogenesis and improved tumor vessel integrity in an animal model. These findings provide evidence that Ac-RLYE is a promising therapeutic drug for solid tumors by targeting tumor vessels.

Materials and Methods

Materials. Cell culture media and supplements were purchased from Invitrogen Life Technologies (Carlsbad, CA). Fetal bovine serum (FBS) was obtained from HyClone Laboratories (Logan, UT). Human recombinant VEGF-A165 was obtained from R&D Systems (Minneapolis, MN). The peptides RLYE, Ac-RLYE, and others were purchased from Peptone (Daeejon, South Korea). Irinotecan hydrochloride (CPT-11) was purchased from Sigma-Aldrich (St. Louis, MO). Aprotinin, leupeptin, EDTA, and phenylmethylsulfonyl fluoride (PMSF) were purchased from Thermo Fisher Scientific (Waltham, MA). Beстатin, arphamenine B, and leuhistin were obtained from Calbiochem (San Diego, CA).

Cell Culture. Human HCT116 colon cancer cells and human umbilical vein endothelial cells (HUVECs) were obtained from American Type Culture Collection (Manassas, VA) and ScienCell Research Laboratories (San Diego, CA), respectively. HCT116 cells were cultured in RPMI medium supplemented with 10% FBS, 1 mM sodium pyruvate, 10 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, and 100 U/ml penicillin-streptomycin antibiotic solution in a humidified atmosphere of 5% CO2 at 37°C. HUVECs were maintained and cultured in M199 as previously described (Baek et al., 2017), and only passages 2–6 were used for all experiments.

In Vitro Angiogenesis Assay. Angiogenic activity was determined by measuring the endothelial cell migration and tube formation as described previously (Baek et al., 2017). Chemotactic migration was analyzed using Boyden chambers. Briefly, the lower surface of the filter of Boyden chambers with 6.5-mm-diameter polycarbonate filters (8-μm pore size) was coated with 10 μg/ml of gelatin. Fresh M199 medium containing FBS (1%) and VEGF (10 ng/ml) was placed in the lower wells. HUVECs were trypsinized and resuspended at a final concentration of 1 × 105 cells/ml in M199 containing PBS (1%) and peptides (1.5 nM or 1 μM to 10 nM). The cell suspension was added into each of the upper wells in a final volume of 100 μl. After incubation at 37°C for 4 hours, the cells that migrated to the lower side of the filter were fixed and stained with hematoxylin and eosin and counted using a phase-contrast microscope. On the other hand, the formation of tube-like structure was determined after culture of HUVECs on growth factor reduced Matrigel according to the manufacturer’s instructions. HUVECs were plated onto the layer of Matrigel at a density of 4.0 × 103 cells/well and stimulated with VEGF (10 ng/ml) alone or in combination with the peptides (1.5 nM) preincubated with either phosphate-buffered saline (PBS) or fresh human serum for 2 hours. After 20 hours, the tube-like structure formation was visualized using a phase-contrast inverted microscope (Olympus IX71; Tokyo, Japan). The degree of tube formation was quantified using Images software (NIH, Bethesda, MA).

Determination of Peptide Degradation and Stability. Human whole blood was collected in sterile centrifuge tubes from healthy volunteers according to protocols approved by the Institutional Review Board at Kangwon National University Hospital (KNUH-2017-01-010-004), and informed consent was obtained from all participants. The investigation conforms to the principles outlined in the Declaration of Helsinki. Whole blood was allowed to clot at 4°C and was then centrifuged at 1500g for 20 minutes at 4°C. The serum was filtered with a sterile filter (0.22 μm; Millipore Corporation, Billerica, MA) and stored in small aliquots at 70°C until further use. For measuring the stability of each peptide in serum, the peptides (100 μg in 50 μl of distilled water) were incubated with 50 μl of filtered human serum in the presence or absence of protease or peptidase inhibitors in a 37°C incubator for the indicated periods. The incubated sample was fractionated by reverse-phase C18 high-performance liquid chromatography (HPLC) with a linear gradient of acetonitrile (Vydac protein and peptide C18 column, 0.1% trifluoroacetic acid in H2O for equilibration, and 0.1% trifluoroacetic acid in acetonitrile for elution). The relative concentrations of the remaining peptides were analyzed by integration of the absorbance at 220 nm as a function of retention time using the Analysis module of the Unicorn software package.

Animal Model of Human Colon Cancer. Seven-week-old male athymic nude mice were purchased from OrientBio (Seongnam, South Korea) and maintained on a standard chow diet ad libitum in a laminar airflow cabinet under specific pathogen-free conditions. Animal experiments were approved by the Institutional Animal Care and Use Committee at Kangwon National University Hospital (KNUH-2017-01-010-004) and informed consent was obtained from all participants. The investigation conforms to the principles outlined in the Declaration of Helsinki. Whole blood was allowed to clot at 4°C and was then centrifuged at 1500g for 20 minutes at 4°C. The serum was filtered with a sterile filter (0.22 μm; Millipore Corporation, Billerica, MA) and stored in small aliquots at 70°C until further use. For measuring the stability of each peptide in serum, the peptides (100 μg in 50 μl of distilled water) were incubated with 50 μl of filtered human serum in the presence or absence of protease or peptidase inhibitors in a 37°C incubator for the indicated periods. The incubated sample was fractionated by reverse-phase C18 high-performance liquid chromatography (HPLC) with a linear gradient of acetonitrile (Vydac protein and peptide C18 column, 0.1% trifluoroacetic acid in H2O for equilibration, and 0.1% trifluoroacetic acid in acetonitrile for elution). The relative concentrations of the remaining peptides were analyzed by integration of the absorbance at 220 nm as a function of retention time using the Analysis module of the Unicorn software package.
were performed in accordance with the guidelines of the Institutional Animal Care and Use Ethics Committee of Kangwon National University (KW-181109-1). Moreover, this investigation conformed to the Guide for the Care and Use of Laboratory Animals published by the United States National Institutes of Health (NIH Publications No. 8023, revised 1978). The sample size for animal experiments was determined according to a previously modified method using a G power program (Charan and Kantharia, 2013). Nude mice were randomly allocated to experimental and control groups and challenged subcutaneously in the left flank with 100 μl of 1 × 10^6 HCT116 human colon carcinoma cells. After the tumor volume grew to at least 50–70 mm³, which occurred within 7 days, the mice were injected intraperitoneally with saline, RLYE (0.5 mg/kg daily), or modified RLYE (0.5 mg/kg daily). Some mice were injected intraperitoneally with Ac-RLYE (0.5 mg/kg daily), RLYE (0.5 mg/kg daily), or in combination with CPT-11 (17 mg/kg every 5 days). The dosage of CPT-11 is one-third of the maximum-tolerated dose (50 mg/kg every 3 days) in the tumor-bearing mouse model and does not induce cytotoxicity when injected intraperitoneally every 3 days (Uchino et al., 2008). Tumor size was measured in two dimensions using calipers. The tumor volume (cubic millimeter) was calculated using the ellipsoid formula: width^2 × length × 0.52 (Baek et al., 2017).

**Tumor Vessel Permeability.** Tumor vessel permeability was assessed using fluorescein isothiocyanate (FITC)-dextran as previously described (Baek et al., 2017). The tumor-bearing mice were treated with peptides alone or in combination with CPT-11 for 18 days and then intravenously injected with 3 mg/mouse FITC-dextran (40 kDa; Sigma-Aldrich). After 10 minutes, the tumors were isolated and fixed briefly in 4% paraformaldehyde, and cryosections of the tumor tissues were prepared to observe vascular leakage under a fluorescence microscope.

**Immunostaining Analysis.** The tumor tissues were fixed in 3.7% paraformaldehyde solution overnight at 4°C, rinsed with PBS at room temperature, incubated in 15% sucrose overnight at 4°C, and transferred to 30% sucrose at 4°C until the tissue sank. The fixed tissues were embedded in Optimal Cutting Tissue compound (Leica Biosystems, Richmond, IL) for 30 minutes at room temperature and subsequently frozen in liquid nitrogen. Frozen sections (30 μm thick) were cut at −20°C, and the slides were stored at −70°C until they were used for immunostaining. The sections were incubated with antibodies for rat anti-CD31 (1:100, no. 553370; DB Pharmingen, San Jose, CA), inducible nitric oxide iNOS (iNOS, 1:100, no. 610600), goat anti-VE-cadherin (1:100, SC-9989; Santa Cruz Biotechnology, Santa Cruz, CA), arginase 1 (1:100, Arg1, SC-166920), F4/80 (1:100, SC-20694), and rabbit anti-NG2 (1:500, ab53292; EMD Millipore) for 2 hours at room temperature. After washing three times with 0.1% Triton X-100 in PBS (10 min/wash), the sections were incubated with Alexa Fluor-, FITC-, or tetramethylrhodamine-isothiocyanate–conjugated secondary antibody (1:1000) for 60–90 minutes at room temperature, counterstained with DAPI (1 μg/ml), and washed five more times with 0.1% Triton X-100 solution (10 min/wash). Some of the tumor sections were subsequently frozen in liquid nitrogen. Frozen sections (30 μm thick) were cut at −20°C, and the slides were stored at −70°C until they were used for immunostaining. The sections were incubated with antibodies for rat anti-CD31 (1:100, no. 553370; DB Pharmingen, San Jose, CA), inducible nitric oxide iNOS (iNOS, 1:100, no. 610600), goat anti-VE-cadherin (1:100, SC-9989; Santa Cruz Biotechnology, Santa Cruz, CA), arginase 1 (1:100, Arg1, SC-166920), F4/80 (1:100, SC-20694), and rabbit anti-NG2 (1:500, ab53292; EMD Millipore) for 2 hours at room temperature. After washing three times with 0.1% Triton X-100 in PBS (10 min/wash), the sections were incubated with Alexa Fluor-, FITC-, or tetramethylrhodamine-isothiocyanate–conjugated secondary antibody (1:1000) for 60–90 minutes at room temperature, counterstained with DAPI (1 μg/ml), and washed five more times with 0.1% Triton X-100 solution (10 min/wash). Some of the tumor sections were also incubated with FITC-isocetin B4 (5 μg/ml; Vector Laboratories, Burlingame, CA) for 1 hour. In addition, the apoptotic cells were detected using a terminal deoxynucleotidyl transferase dUTP nick-end labeling (TUNEL) kit (Roche Applied Science, Indianapolis, IN). The slides were mounted with Permount solution (Thermo Fisher Scientific, San Jose, CA), arginase 1 (1:100, Arg1, SC-166920), F4/80 (1:100, SC-20694), and rabbit anti-NG2 (1:500, ab53292; EMD Millipore) for 2 hours at room temperature. After washing three times with 0.1% Triton X-100 in PBS (10 min/wash), the sections were incubated with Alexa Fluor-, FITC-, or tetramethylrhodamine-isothiocyanate–conjugated secondary antibody (1:1000) for 60–90 minutes at room temperature, counterstained with DAPI (1 μg/ml), and washed five more times with 0.1% Triton X-100 solution (10 min/wash). Some of the tumor sections were also incubated with FITC-isocetin B4 (5 μg/ml; Vector Laboratories, Burlingame, CA) for 1 hour. In addition, the apoptotic cells were detected using a terminal deoxynucleotidyl transferase dUTP nick-end labeling (TUNEL) kit (Roche Applied Science, Indianapolis, IN). The slides were mounted with Permount solution (Thermo Fisher Scientific) and analyzed using the Zeiss LSM 580 laser scanning confocal microscope with AiryScan (Carl Zeiss, Oberkochen, Germany). Images were acquired with pinhole settings of 1 Airy unit, on a GaAsP-PMT detector with a gain setting of 800, a pixel dwell time of 2.06 μs, and no averaging. Airyscan images were acquired with 2% of maximum laser power for argon-ion (488 nm), helium-neon (633 and 543 nm), and diode (405 nm) laser lines. The image acquisition parameters were kept constant between the control and treated groups. Co-localization of CD31 and VE-cadherin was assessed by Pearson’s correlation coefficient using the ZEN software in a blinded investigation.

**Statistical Analysis.** The quantitative data are expressed as mean ± S.D. of at least three independent experiments performed in triplicate. Image analysis was performed by three blinded observers, and no samples were excluded from the analysis. Statistical analyses were performed using GraphPad Prism 6 (La Jolla, San Diego, CA). Statistical significance was determined using either the unpaired student’s t test or one-way ANOVA, followed by Tukey’s post-hoc test, depending on the number of experimental groups analyzed. Differences were considered statistically significant at P < 0.05. For all statistical analyses, the appropriate statistical tests were chosen, and the data met the assumptions of the test, and the variance between the statistically compared groups was similar.

**Results**

**RLYE is Degraded by Heat-Labile Serum Factors.** Since small peptides are likely to be unstable in the serum due to the presence of serum-derived peptidases and therefore rapidly cleared from blood circulation, we first examined the stability of the VEGFR-2 antagonist RLYE (structure shown in Fig. 1A) in fresh human serum using HPLC-based spectrophotometry after incubation for different periods at 37°C. The characteristic peak of RLYE was rapidly reduced in the serum with a half-life (t_1/2) of 73 minutes, although it was quite stable in PBS (Fig. 1B), suggesting that this peptide is degraded or absorbed by certain biomolecules present in the serum. We next examined whether the stability of the peptide was affected by heat-labile serum factors, such as peptidases or proteases. The serum was preheated at different temperatures for 10 minutes and incubated with RLYE for 2 hours, followed by quantitation of the amount of the remaining peptide. The peptide stability remained unchanged only when incubated with serum preheated over 70°C (Fig. 1C). These data suggest that RLYE may be degraded or destabilized by heat-labile serum factors.

**RLYE is Degraded by Aminopeptidases B and N.** Since enzymes are generally neutralized by heating over about 70°C, we examined the identity of the proteins, including enzymes, which are involved in the degradation or destabilization of RLYE. When incubated with albumin, the most abundant protein in serum, RLYE, remained stable (Fig. 2A), suggesting that the stability of RLYE is not affected by albumin; however, coinubcation with protease inhibitors, such as aprotinin, leupeptin, PMSF, or EDTA, failed to restore the decreased peak height of RLYE that was observed upon incubation with serum (Fig. 2A), suggesting that serum proteases are not involved in the destabilization of RLYE. Based on the amino acid sequence of the peptide, we hypothesized that aminopeptidases B and N, which cleave Arg at the N-terminal residue, may contribute to the degradation of RLYE. Notably, bestatin, an inhibitor of aminopeptidases B and N, completely restored the decreased peak height of RLYE incubated with serum (Fig. 2B). These results suggest that aminopeptidases B and N are responsible for degradation of RLYE in the bloodstream. We next examined which of these aminopeptidases is predominantly involved in the destabilization of RLYE in serum using their specific inhibitors. Destabilization of RLYE in serum was partially inhibited by both aminopeptidase B-specific inhibitor (arphamenine B) and N-specific inhibitor (leuhistin), and the inhibitory effect of leuhistin was slightly higher than that of arphamenine B; however, combined treatment with both inhibitors completely blocked the destabilization of RLYE in serum (Fig. 2C). These
results suggest that RLYE is degraded by both serum amino-peptidases B and N.

N-Terminal Modification Stabilizes RLYE and Potentiates its Antiangiogenic Activity. To improve the stability of the peptide from serum peptidase-mediated degradation, RLYE was modified at either the N- or C-terminal residue. N-terminal acetylation (Ac-RLYE) significantly increased the half-life of RLYE (1.2 hours) to approximately 8.8 hours in fresh serum, whereas the C-terminal amidation (RLYE-NH₂) did not effectively change the serum stability of RLYE (Fig. 3, A and C). Similar to Ac-RLYE, R₃₄₀LYE, in which L-Arg of RLYE is replaced with its inactive stereoisomer D-Arg, also had an increased serum half-life of 7.0 hours compared with that of RLYE, indicating that R₃₄₀LYE is stable in serum, albeit slightly less compared with Ac-RLYE (Fig. 3, B and C); however, modification of RLYE at both N and C termini (Ac-RLYE-NH₂) increased its serum half-life to 9.4 hours, which was slightly longer than that of Ac-RLYE and much longer than that of RLYE-NH₂ (Fig. 3C), which suggests that the N-terminal L-Arg residue is a critical determinant of the stability of RLYE in serum. We next examined the effects of RLYE and its modified versions on VEGF-A–induced endothelial migration, which is a typical characteristic of in vitro angiogenesis. Treatment of HUVECs with 1.5 nM of Ac-RLYE and R₃₄₀LYE showed slightly higher inhibitory effects of 95.8% and 91.4%, respectively, than RLYE (85.4%) on VEGF-A–induced endothelial cell migration; however, RLYE-NH₂ revealed a lower inhibitory effect (79.7%) than RLYE (Fig. 3C). On the other hand, Ac-RLYE-NH₂ had a significantly lower inhibitory effect on VEGF-A–induced endothelial cell migration compared with that of RLYE (11.3% vs. 85.4%). To further compare the antiangiogenic activities of all the peptides, the IC₅₀ values were determined against VEGF-A–induced endothelial cell migration. The IC₅₀ values of Ac-RLYE and R₃₄₀LYE were approximately 37.1 pM [95% confidence interval (CI): 69.1–44.7 pM] and 52.5 pM (95% CI: 39.8–70.8), respectively, which were lower than that of RLYE (IC₅₀: 89.1 pM, 95% CI: 69.1–116.9 pM); however, the IC₅₀ values of RLYE-NH₂ and Ac-RLYE-NH₂ were 326.6 pM (95% CI: 224.8–475.3 pM) and >1.0 nM, respectively, much higher than that of RLYE (Fig. 3C; Supplemental Fig. 1). Furthermore, we compared the antiangiogenic activity of the peptides after preincubation with PBS or

Fig. 1. RLYE is degraded by a heat-labile serum factor. (A) Chemical structure of RLYE. (B) RLYE was incubated with PBS or healthy human serum at 37°C for the indicated times. The reaction mixture was fractionated by reverse-phase HPLC, and peptide concentration was analyzed by the integration of absorbance at 220 nm as a function of retention (n = 3). Inserted peaks show a typical chromatogram of RLYE that was incubated in fresh human serum for the indicated times. (C) Human serum was preheated at the indicated temperature for 10 minute and then incubated with RLYE at 37°C for 2 hours. Representative spectra of the remaining RLYE were obtained via HPLC-based analysis.

Fig. 2. Degradation of RLYE in serum is blocked by inhibitors of aminopeptidases B and N. (A) RLYE was incubated in PBS, human serum, or 50% human albumin solution in the presence or absence of aprotinin (1 μM), EDTA (1 mM), leupeptin (100 μM), or PMSF (1 mM) at 37°C for 4 hours. The remaining peptide was determined by HPLC-based analysis. (B) RLYE was incubated in PBS or human serum in the absence or presence of bestatin (50 μM) at 37°C for 4 hours and analyzed by HPLC. (C) The peptide was incubated in PBS or human serum in the absence or presence of arphamenine B (50 μM), leuhistin (50 μM), or a combination of both at 37°C for 4 hours and analyzed by HPLC. (A–C) All the peaks are representative spectra of two independent experiments.
human serum for 2 hours to mimic the in vivo system of circulating blood. When preincubated either with PBS or human serum, R(D)LYE and Ac-RLYE strongly inhibited VEGF-induced tube-like structure formation, whereas RLYE had potent anti-angiogenic activity when preincubated with PBS but showed only partial activity with human serum (Fig. 3D), suggesting that R(D)LYE and Ac-RLYE have more potent anti-angiogenic activity than RLYE in serum. Collectively, our results suggest that the N-terminal modification greatly stabilizes RLYE in circulating blood and effectively inhibits VEGF-A-induced angiogenesis.

Ac-RLYE and R(D)LYE Potentially Inhibit Tumor Growth and Angiogenesis. We examined the antitumor effects of Ac-RLYE and R(D)LYE in a human colorectal tumor xenograft model. Treatment with both modified peptides significantly inhibited tumor growth and decreased tumor size and weight compared with RLYE treatment, and the antitumor effects of Ac-RLYE were slightly greater than those of R(D)LYE (Fig. 4, A–C). We next assessed the inhibitory effects of these peptides on tumor angiogenesis. Immunohistochemical analysis of CD31, an endothelial specific marker, showed that both modified peptides significantly decreased blood vessel formation in the tumor tissues compared with RLYE, and the effect of Ac-RLYE was greater than that of R(D)LYE (Fig. 4, D and E). Therefore, these data suggest that Ac-RLYE has more a potent antitumor effect than the other peptides via effective inhibition of tumor angiogenesis.

Ac-RLYE Improves Normalization of Tumor Vessels. Since tumor angiogenesis forms the abnormal vasculature in conjunction with increased vascular permeability and leakage, leading to tumor progression and metastasis (Jain, 2005), we evaluated the effect of Ac-RLYE on the vascular permeability and leakage in tumors using FITC-dextran. Treatment of tumor-bearing mice with Ac-RLYE significantly reduced tumor vessel leakage compared with that of saline control, and this effect was greater than that of RLYE (Fig. 5, A and B). Vascular permeability is regulated by abnormal vascular structures, such as loss of endothelial cell junctions and lack of pericytes (Hellström et al., 2001). As expected, we found that treatment with Ac-RLYE resulted in a high degree of colocalization of CD31 and VE-cadherin, an endothelial cell junction protein, as well as a significant decrease in CD31 immunoreactivity compared with RLYE treatment (Fig. 5, C and D). Moreover, Ac-RLYE treatment resulted in increased pericyte coverage on tumor vessels compared with RLYE treatment, as determined by staining with the pericyte marker NG2 (Ozerdem et al., 2001) (Fig. 5, E and F). These results suggest that N-acetylation improves the effect of RLYE on tumor vessel normalization through enhancement of endothelial cell junctions and pericyte coverage.

Ac-RLYE Sensitizes Tumor to CPT-11. Since reduced vascular leakage via tumor vessel normalization increases drug delivery to solid tumors and facilitates chemotherapeutic efficacy (Jain, 2005; Dineen et al., 2008; Carmeliet and Jain, 2011), we examined the combined effect of the peptides and an anticancer drug CPT-11 (17 mg/kg every 5 days) on tumor progression. Cotreatment with RLYE and CPT-11 revealed a synergistic inhibition of tumor growth, and this synergistic
effect was further augmented by replacement of RLYE with Ac-RLYE (Fig. 6A). Consistent with this, TUNEL assay showed that apoptotic cells were synergistically augmented in tumors of mice treated with a combination of Ac-RLYE and CPT-11, and the synergistic apoptosis was greater than that induced by cotreatment with RLYE and CPT-11 (Fig. 6, A–C); however, treatment with Ac-RLYE, CTP-11, and both together did not significantly change the serum levels of the hepatotoxicity markers alanine aminotransferase and aspartate aminotransferase (Fig. 6D) and the body weights (23.5 ± 0.6, 24.1 ± 0.8, and 22.8 ± 0.7 g, respectively), in concordance with the results shown in a previous study (Uchino et al., 2008). These results suggest that the N-acetylation enhances the effect of RLYE on CPT-11-mediated chemotherapeutic efficacy without significant toxicity in a mouse model.

Ac-RLYE Inhibits Infiltration of Macrophages and their Polarization to M2 Phenotype. Tumor-associated macrophages (TAMs) express VEGFR-2 (Dineen et al., 2008) and play an important role in tumor angiogenesis by polarization from the cytotoxic M1 to the angiogenic M2 phenotype (Riabov et al., 2014). We examined whether Ac-RLYE regulates infiltration of macrophages into tumors and their phenotypic polarization. Treatment with Ac-RLYE significantly decreased infiltration of F4/80-positive macrophages into tumors compared with injection of saline (Fig. 7, A and B). TAMs in mice treated with Ac-RLYE expressed low levels of the M2 macrophage marker Arg1 and high levels of the M1 macrophage marker iNOS compared with TAMs in saline-treated mice (Fig. 7, A and C–E). CPT-11 treatment resulted in a significant increase in infiltration of macrophages, which expressed high levels of Arg1 and low levels of iNOS compared with those in control tumors, and these gene expression patterns were inversely regulated by cotreatment with Ac-RLYE (Fig. 7, A and C–E). Therefore, treatment with Ac-RLYE inhibited infiltration of macrophages and polarization of TAMs to the M2 phenotype (Fig. 7, B and F), possibly resulting in an increase in TAM-induced tumor cytotoxicity.

Discussion

Since formation of the tumor vascular network plays a critical role in tumor growth and metastasis, many angiogenic inhibitors have been developed and clinically used for treating solid tumors (Kamba and McDonald, 2007; Verheul and Pinedo, 2007; Cook and Figg, 2010; Taugourdeau-Raymond et al., 2012; McIntyre and Harris, 2015). The tumor vasculature created by tumor-derived VEGF exhibits a spectrum of morphologic and functional abnormalities characterized by loss of vessel hierarchy, increased tortuosity, poor perfusion, instability, and increased vascular leakage (McDonald and Baluk, 2005). Thus, antiangiogenic agents not only inhibit tumor angiogenesis but also normalize the tumor vasculature, resulting in improved chemotherapeutic efficacy by enhancing the delivery of anticancer drugs to tumors.

We previously demonstrated that the tetrapeptide RLYE effectively suppressed tumor neovascularization by blocking the interaction between VEGF-A and VEGFR-2, resulting in inhibition of tumor growth and metastasis in a tumor-bearing mouse model (Baek et al., 2015, 2017); however, we found that RLYE was unstable and readily degraded with a half-life of approximately 1.2 hours when incubated in human serum. This short half-life was due to serum aminopeptidases B and N, which cleave the N-terminal Arg
residue of the peptide. Since these enzyme activities are elevated in the sera of patients with breast and pancreatic cancer (Dineen et al., 2008; Martínez-Martos et al., 2011), RLYE would need to be modified to be resistant to both aminopeptidases for clinical use in tumor treatment. To address this need, we developed N-terminal modified peptides, Ac-RLYE and R(D)LYE, with increased stability of 7.3 and 5.8 folds, respectively, in serum compared with RLYE. Ac-RLYE had more potent inhibitory activity than R(D)LYE against VEGF-A-induced in vitro angiogenesis. Moreover, Ac-RLYE effectively inhibited tumor angiogenesis and tumor growth, as well as improved tumor vessel normalization, resulting in enhanced therapeutic efficacy when cotreated with the chemotherapeutic drug CPT-11. As demonstrated by clinical evidence that antiangiogenic agents show antitumor activity mostly in combination with chemotherapeutics (Sengupta et al., 2015; Margonis et al., 2017), our findings strongly suggest that Ac-RLYE could be used as a potential drug for antiangiogenic tumor therapy or in combination with chemotherapy.

Tumor angiogenesis progresses from the pre-existing normal vessels surrounding the tumor under the influence of...
proangiogenic growth factors secreted by the tumor cells. Among the angiogenic stimulators, the VEGF family stimulators are the most potent mitogenic and angiogenic activators (Hicklin and Ellis, 2005). Of the VEGF isoforms, VEGF-A is the most important factor controlling tumor angiogenesis and vascular network (Papetti and Herman, 2002; Folkman, 2007). VEGF-A binds to both VEGFR-1 and VEGFR-2, which are expressed mainly in endothelial cells. VEGFR-1 has a high binding affinity for VEGF-A, which is one order higher than that of VEGFR-2, whereas its angiogenic activity is approximately 10-fold weaker than that of VEGFR-2 (Sawano et al., 1996; Shibuya, 2011). Therefore, VEGFR-2 plays a crucial role not only in physiologic angiogenesis during wound healing and embryogenesis but also in pathologic angiogenesis during tumor growth and metastasis (Kerbel, 2008). Thus, VEGFR-2 is a potential therapeutic target for inhibiting tumor angiogenesis and tumor progression (Roland et al., 2009). We previously demonstrated that RLYE interferes with the interaction between VEGF-A and VEGFR-2, leading to endothelial dysfunction. Since RLYE was rapidly degraded by serum-derived aminopeptidases B and N, we developed Ac-RLYE, a peptide with increased stability in serum, which inhibited tumor angiogenesis even more and improved the tumor vessel normalization.

RLYE binds specifically to VEGFR-2, but not VEGFR-1, at the interface between the immunoglobulin homology domains D2 and D3 (Baek et al., 2017), which is known to be the binding site for VEGF-A/C (Leppänen et al., 2010). Notably, both the terminal residues of RLYE, Arg and Glu, bind electrostatically to Glu140 and Lys286 of VEGFR-2, respectively, and Lys286 is crucial for the formation of a salt bridge with Glu64 of VEGF-A (Leppänen et al., 2010). Ac-RLYE was stable in serum and increased antiangiogenic activity, indicating that the N-terminal acetylation does not affect interaction between Ac-RLYE and VEGFR-2. On the other hand, RLYE-NH2 was not stable in serum but partially decreased antiangiogenic activity, whereas Ac-RLYE-NH2 was more stable in serum compared with the other modified peptides but showed markedly decreased antiangiogenic activity compared with RLYE. These phenomena can be explained by two possibilities. First, RLYE can be degraded not only by aminopeptidases B and N, but also partially by other enzymes, including glutamate carboxypeptidase, which is a secreted enzyme that hydrolyzes the C-terminal Glu of peptides in circulating blood (Lee et al., 2016); however, we cannot exclude another possibility that it can be destabilized by unknown endopeptidases because half-life of Ac-RLYE-NH2 was less than 10 hours when incubated with serum. Second, both positive and negative charges at the termini of the peptide are important for its biologic activity owing to their essential contribution to interaction with VEGFR-2 (Leppänen et al., 2010; Baek et al., 2017). This...
structural and binding information is important for developing nonpeptidic small molecules targeting VEGFR-2, with strong resistance to the blood peptidases.

Since tumor blood vessels are heterogeneous, tortuous, and irregularly branched, they are structurally and functionally abnormal (Jain, 2005). The tumor vessels are poorly perfused, hyperpermeable, and leaky with loss of interendothelial junctions and less coverage of pericytes, thereby limiting the delivery of cytotoxic agents to tumors and hence decreasing chemotherapeutic efficacy (Carmeliet and Jain, 2011). In general, antiangiogenic drugs targeting the VEGF-A/VEGFR-2 system not only inhibit tumor angiogenesis, but they also promote tumor vascular normalization, leading to an increase in drug delivery and efficacy when combined with chemotherapeutic drugs (Jain, 2005; Dineen et al., 2008; Carmeliet and Jain, 2011). Others and we have demonstrated that combination therapy of the antiangiogenic drug bevacinuzumab or vascular leakage blocker Sac-1004 with anticancer drugs increased drug delivery through tumor vessel normalization and hence improved the antitumor efficacy (Dickson et al., 2007; Yanagisawa et al., 2010; Agrawal et al., 2014). Similarly, we demonstrated that Ac-RLYE fostered vascular normalization through improvement of endothelial junctions and pericyte coverage, resulting in increased tumor-cell apoptosis and therapeutic efficacy of coadministered CPT-11.

Accumulating evidence suggests that the VEGF-A/VEGFR-2 axis is also crucial for the immune modulation of the tumor microenvironment, in addition to its effect on the vasculature (Dineen et al., 2008; Roland et al., 2009). The VEGF-A/VEGFR-2 axis is not only important for tumor vascularization, but it is also a key factor in the inhibition of the recognition and destruction of tumor cells via negative regulation of the immune system (Ohm and Carbone, 2001). In fact, VEGF-A interferes with cell-mediated immunity by decreasing differentiation, recruitment, function of T cells, and development of T cells from early hematopoietic progenitor cells in tumors to chemotherapeutic drugs increases infiltration of macrophages expressing the M2-marker MCR1 into tumor, leading to increased angiogenesis and limited chemotherapeutic efficacy, probably by increasing hypoxia-inducible factor-1α (HIF-1α)-dependent CXCL12 and VEGF expression (Hughes et al., 2015; Zhao et al., 2017). These results are consistent with our data showing an increase in M2-type macrophage infiltration in tumor-bearing mice receiving CPT-11; however, the CPT-11-induced increase in macrophage infiltration and M1/M2 polarization could be blocked or reprogrammed via tumor vessel normalization, decreased vascular leakiness, and favorable tumor environment (decreased HIF-1α level) by treatment with antiangiogenic drugs, including Ac-RLYE (Dineen et al., 2008; De Palma and Lewis, 2013; Baek et al., 2017). Based on these results, combination therapy of Ac-RLYE with CPT-11 or other chemotherapeutic drugs is a potential approach in the treatment of cancer via increased TAM-induced tumor cytotoxicity.

Macrophages isolated from tumor-bearing mice express both VEGFR-1 and VEGFR-2, whereas macrophages harvested from non–tumor-bearing animals express only VEGFR-1 (Dineen et al., 2008), suggesting that VEGFR-2 is essential for macrophage infiltration into tumors. Indeed, the monoclonal antibody against VEGFR-2, ramucirumab, is clinically used for treating patients with different tumor types (April et al., 2014). This finding suggests that the specific blockade of VEGFR-2 activation might be more effective than other antiangiogenic strategies, including VEGFR-2 kinase inhibitors with relatively low specificity (Verheul and Pinedo, 2007; Cook and Figg, 2010) and anti-VEGF antibodies with several side effects (Kamba and McDonald, 2007; Taugourdeau-Raymond et al., 2012). Thus, specific inhibitors of VEGFR-2 overcome not only tumor angiogenesis, but they also tumor immune privilege, without serious systemic toxicity (Roland et al., 2009). Our data showed that Ac-RLYE, an N-terminal acetylated peptide of RLYE specifically bound to VEGFR-2 (Baek et al., 2017), potentially inhibited infiltration of macrophages into tumors and their polarization to the M2 phenotype, which exerts angiogenic and immunosuppressive activities (Riabov et al., 2014). These findings suggest that Ac-RLYE is a potential agent for preventing TAM-mediated creation of unfavorable tumor microenvironment, resulting in enhanced tumor cytotoxicity and decreased tumor angiogenesis.

In conclusion, the present study demonstrates that N-terminal acetylation significantly potentiated the effect of RLYE on angiogenesis, vascular normalization, and tumor immunity in solid tumors because of its increased serum stability. As a result, Ac-RLYE effectively inhibited tumor progression both by inhibiting tumor angiogenesis and by improving tumor immunity and drug delivery in combination therapy with anticancer drugs. Together, our findings provide evidence that Ac-RLYE can be used as a potential VEGFR-2...
antagonist for anti-angiogenic tumor therapy and enhanced chemotherapeutic drug delivery and efficacy.
