ABSTRACT
We recently described 3-amino-5-chloro-6-methoxy-4-methylthieno[2,3-b]pyridine-2-carboxylic acid cyclopropylamide (LY2033298) as a novel allosteric modulator of M₄ muscarinic acetylcholine (ACh) receptors (mAChRs) on the basis of its ability to preferentially potentiate the actions of ACh at the M₄ mAChR subtype. In the current study, we show that LY2033298 can also bind to the M₂ mAChR and mediate robust positive or negative allosteric effects depending on the orthosteric ligand used as a probe of receptor activity. This finding of striking “probe-dependence” indicates that the previously-described selectivity of the modulator does not arise as a consequence of selective affinity for a poorly conserved allosteric site, but rather due to subtype-selective cooperativity with ACh upon interaction with a common allosteric binding site. Moreover, a comparison of the effects of the modulator on orthosteric ligand affinity relative to signaling through a [³⁵S]GTPγS or extracellular signal-regulated kinases 1/2 (ERK1/2) phosphorylation assay at the M₂ mAChR revealed that, although the effects on binding were positive in all instances, the effects on signaling were either positive or strongly negative depending on the agonist and the pathway. Mutational analysis identified residues Y₁₇₇ and W₉₉³.₂⁸ as contributing to the binding of LY2033298, whereas the orthosteric site residues, Y₁₀₄³.₃₃ and Y₄₀₃₆.₅₁ contributed to the ability of the ligand to impose pathway-biased modulation. Collectively, these findings have important implications for the detection and validation of allosteric modulators of G protein-coupled receptors (GPCRs), because they highlight the potential for ligand misclassification or lack of appreciation of off-target allosteric activities.
INTRODUCTION

The mAChRs are prototypical Family A GPCRs. Five mAChR subtypes have been identified and classified functionally on the basis of G protein signal transduction preferences; M₁, M₃ and M₅ mAChR subtypes preferentially activate G_{q/11} proteins, whereas M₂ and M₄ mAChRs signal preferentially through G_{i/o} proteins (Caulfield, 1993). However, all five mAChRs are promiscuous in their coupling preferences and exhibit signaling behavior that extends beyond the simple G protein-second messenger paradigm, including the recruitment of convergent pathways such as the MAP kinases (Lanzafame et al., 2003). Because these receptors are widely expressed throughout the CNS and the periphery, they have emerged as therapeutic targets for treatment of a diverse range of pathologies, including schizophrenia, Alzheimer’s disease, pain, respiratory disorders, bladder dysfunction, and irritable bowel syndrome (Eglen et al., 2001; Wess et al., 2007). However, a major drawback to the selective targeting of the mAChRs has been the high degree of homology conservation within the orthosteric (ACh-binding) pocket.

One approach showing promise in overcoming some of the difficulties associated with selective mAChR drug targeting is to focus on allosteric binding sites. Indeed, the mAChRs are one of the best-characterized model systems for understanding the actions of small molecule allosteric modulators of GPCRs, and a relatively rich allosteric pharmacology has emerged in recent years for various mAChR subtypes (Birdsall et al., 2005; Gregory et al., 2007; Conn et al., 2009). Commonly-proposed advantages of targeting receptor allosteric sites include the possibility of greater selectivity due to lower sequence conservation within allosteric pockets across subtypes of a given GPCR, as well as the potential to fine-tune physiological signaling in a more spatial and temporally-selective manner (Christopoulos, 2002; May et al., 2007c). However, it is often underappreciated that selectivity in the actions
of allosteric modulators can also be achieved through the expression of selective cooperativity (positive or negative) between allosteric and orthosteric ligands at one receptor subtype while retaining neutral cooperativity at all other subtypes of the same receptor family (Lazareno et al., 1996). That is, it is possible for an allosteric site to also be conserved across subtypes of a given GPCR, but the magnitude and direction of the allosteric effect can vary dramatically between these subtypes.

We have recently described the *in vitro* and *in vivo* pharmacological characteristics of a novel allosteric modulator, LY2033298, which is an allosteric agonist and a selective potentiator of the actions of ACh at the human M₄ mAChR but exhibits minimal interaction with the endogenous agonist at other mAChR subtypes (Chan et al., 2008; Nawaratne et al., 2008; 2010; Leach et al., 2010; 2011). Interestingly, when examining the potential for species variability in the actions of this modulator between human and rodent M₄ mAChRs, we found that the variability could be attributed to differences in the cooperativity between the modulator and ACh between species, and not due to differences in the allosteric binding pocket between the human and rodent receptors (Suratman et al., 2011). Moreover, we also noted striking differences in the magnitude of the allosteric effect depending on the nature of the orthosteric ligand used. For instance, LY2033298 caused robust potentiation of the actions of the agonists, ACh and oxotremorine, at M₄ mAChRs, but was only weakly positive when combined with the agonist, xanomeline, neutral when tested against the antagonist, [³H]quinuclidinyl benzylate ([³H]QNB), and weakly negative when combined with the antagonist, N-[³H]methylscopolamine ([³H]NMS) (Leach et al., 2010; Suratman et al., 2011). A change in the nature and extent of allosteric modulation at a given receptor depending on the type of orthosteric ligand used is referred to as “probe dependence” (Kenakin, 2005;
Keov et al., 2011) and has substantial implications for the detection, validation and potential therapeutic utility of allosteric ligands.

Given these findings, the aim of the current study was to re-evaluate the notion of allosteric modulator selectivity in the context of a receptor that is closely related to the M₄ mAChR, but which shows less potential for allosteric interaction between LY2033298 and the endogenous agonist; a finding that reflects either variability in the allosteric binding pocket or else a manifestation of differential cooperativity between subtypes. For this purpose, we chose the M₂ mAChR. By utilizing different agonists and antagonists, as well as a series of mutant M₂ mAChR, we provide evidence for a “common” allosteric binding pocket utilized by LY2033298 across mAChR subtypes, and also reveal striking examples of probe dependence that have wider implications for allosteric ligand drug discovery.
MATERIALS AND METHODS

Materials

Dulbecco’s modified Eagle’s medium, penicillin/streptomycin, and hygromycin-B were purchased from Invitrogen. Fetal bovine serum (FBS) was purchased from ThermoTrace (Melbourne, Victoria, Australia). [3H]NMS (70.0 Ci/mmol) and [3H]QNB (120 Ci/mmol) were purchased from PerkinElmer Life Sciences. [35S] guanosine 5′-O-[gamma-thio]triphosphate ([35S]GTPγS; >1000 Ci/mmoll) was purchased from PerkinElmer Life Sciences and Amersham Biosciences. The Sure-FireTM cellular ERK1/2 assay kits were a generous gift from TGR BioSciences (Adelaide, Australia). AlphaScreenTM reagents were from PerkinElmer Life Sciences. LY2033298, and xanomeline tartrate were synthesized in-house at Eli Lilly (Indianapolis, IN). All other chemicals were from Sigma Chemical Co. (St. Louis, MO).

Receptor mutagenesis, cell culture and membrane preparation

FlpIn Chinese hamster ovary (CHO) cells stably expressing muscarinic M2 mAChRs (M2 mAChR FlpIn-CHO) wild type (WT) or mutant were generated and cultured as described previously (Stewart et al., 2009). Cell membranes were prepared as described previously (Valant et al., 2008).

Radioligand Equilibrium Binding Assays

M2 mAChR FlpIn-CHO membrane homogenates (5-20 μg) were incubated in a 500 μl total volume of assay buffer containing either [3H]NMS (0.5 nM) or [3H]QNB (0.5 nM) and a range of concentrations of LY2033298 (10 nM to 100 μM) at 30 °C for 90 min. Radioligand saturation binding and affinity parameters in these cells have been reported previously.
(Gregory et al., 2010). Interaction binding studies were also performed between [3H]NMS, an IC$_{20}$ concentration of various mAChR agonists (ACh, oxotremorine, oxotremorine-M, tetramethylammonium, pilocarpine, xanomeline or McN-A-343), and increasing concentrations of LY2033298 by co-incubating 20 µg of M$_2$ mAChR FlpIn-CHO membrane in the presence of guanosine-5′-(βγ-imino)triphosphate (Gpp(NH)p), as described previously (Nawaratne et al., 2010). For all experiments, nonspecific binding was defined by 10 µM atropine, and the effects of vehicle were also determined. Incubation was terminated by rapid filtration through Whatman GF/B filters using a Brandell cell harvester (Gaithersburg, MD). Filters were washed three times with 3 ml aliquots of ice-cold 0.9% NaCl buffer and dried before the addition of 4 ml of scintillation mixture (Ultima Gold, PerkinElmer Life Sciences). Vials were then left to stand until the filters became uniformly translucent before radioactivity was determined in dpm using scintillation counting.

[3H]NMS Dissociation Kinetic Assays

M$_2$ mAChR FlpIn-CHO cell membranes (20 µg for wild type or 5 µg for Y177A) were equilibrated with [3H]NMS (0.5 nM) in a 1 ml total volume of assay buffer for 90 min at 30°C. Atropine (10 µM) alone or in the presence of LY2033298 was then added at various time points to prevent the reassociation of [3H]NMS with the receptor. In subsequent experiments designed to investigate the effect of a range of modulator concentrations on [3H]NMS dissociation rate, a “two-point kinetic” experimental paradigm was used where the effect of increasing concentrations of LY2033298 on [3H]NMS dissociation was determined at 4 and 40 min. This approach is valid to determine [3H]NMS dissociation rate constants if the full time course of radioligand dissociation is monophasic both in the absence and presence of modulator (Kostenis et al., 1996) (Lazareno et al., 1995); this was the case in our current study. All other details of these assays are as described previously (Valant et al.,
2008). Termination of the reaction and determination of radioactivity were performed as described above.

[\textsuperscript{3}H]NMS Association Kinetic Assay

A two-point kinetic experimental paradigm was used where the effect of increasing concentrations of allosteric modulator on [\textsuperscript{3}H]NMS association was determined at 3 and 30 min. M\textsubscript{2} mAChR FlpIn-CHO cell membranes (20 µg) were added into a 1 ml total volume of assay buffer at 30 °C containing [\textsuperscript{3}H]NMS (0.5 nM) alone or in the presence of a range of concentrations of LY2033298 at 3 and 30 min. Termination of the reaction and determination of radioactivity were performed as described above.

[\textsuperscript{35}S]GTP\gamma S Binding Assay

M\textsubscript{2} mAChR FlpIn-CHO cell membranes (5-25 µg) were equilibrated in a 500 µl total volume of assay buffer containing 10 µM guanosine 5'-diphosphate and a range of concentrations of ligands (ACh, oxotremorine, oxotremorine-M, tetramethylammonium, pilocarpine, xanomeline or McN-A-343) in the absence or presence of LY2033298 (0.1 to 10 µM) at 30 °C for 60 min. After this time, 50 µl of [\textsuperscript{35}S]GTP\gamma S (1 nM) was added, and incubation continued for 30 min at 30 °C. Termination of the reaction and determination of radioactivity were performed as described above.

ERK1/2 Phosphorylation Assay

These assays were performed using the AlphaScreen-based SureFire kit as described in detail previously (May et al., 2007a) (Avlani et al., 2007). For each agonist, the pERK1/2 response was determined to peak between 5 and 8 min (data not shown), and subsequent concentration-response curves were constructed at the peak time point. All data were
expressed as a percentage of ERK1/2 phosphorylation mediated after a 6 min exposure to Dulbecco’s modified Eagle’s medium containing 3% FBS or normalized to the maximal response of the endogenous agonist, ACh, when specified.

Data analysis

Computerized nonlinear regression was performed using Prism 5.03 (GraphPad Software, San Diego, CA). Radioligand binding curves for interaction with LY2033298 were fitted to an allosteric ternary complex model (Eq. 1) to derive estimates of allosteric modulator affinity (K_B), cooperativity between the modulator and the radioligand (α’) or the agonist (α); values of α or α’ > 1 denote positive cooperativity, whereas values of 0 < α or α’ < 1 denote negative cooperativity (Christopoulos et al., 2002; May et al., 2007b):

\[
E = \frac{B_{max}[A]}{[A] + \left( \frac{K_A K_B}{\alpha[B] + K_B} \right) \left( 1 + \frac{[I]}{K_I} + \frac{[B]}{K_B} + \frac{\alpha[I][B]}{K_I K_B} \right)}
\]

where K_A, K_B and K_I represent the equilibrium dissociation constants of the radioligand, allosteric ligand and second (unlabeled) orthosteric ligand, respectively, and [A], [B] and [I] denote their respective concentrations. Interaction studies between radioligand and the modulator in absence of inhibitor, i.e. [I] = 0, allowed determination of α’.

Dissociation and association kinetic data were fitted to monoexponential functions to derive observed rate constants of either dissociation or association. Finally for whole cell functional studies, the interaction between the orthosteric agonists and LY2033298 was fitted to the following two forms of an operational model of allosterism and agonism (Aurelio et al., 2009; Leach et al., 2007) to derive functional estimates of modulator affinity, cooperativity and efficacy:
MOL #74872

\[
E = \frac{E_m (\tau_A [A] (K_B + \alpha \beta [B]) + \tau_B [B] K_A})^n}{(A)K_B + K_A K_B + [B] K_A + \alpha [A][B])^n + (\tau_A [A] (K_B + \alpha \beta [B]) + \tau_B [B] K_A})^n}
\]

Equation 2

\[
E = \frac{E_m (\tau_A [A] (K_B + \alpha \beta [B]) + \tau_B [B] EC_{50})^n}{EC_{50} [K_B + [B])^n + (\tau_A [A] (K_B + \alpha \beta [B]) + \tau_B [B] EC_{50})^n}
\]

Equation 3

where \(E_m\) is the maximum attainable system response for the pathway under investigation, [A] and [B] are the concentrations of orthosteric agonist and allosteric modulator/agonist, respectively, \(K_B\) is the dissociation constant of the allosteric modulator, \(EC_{50}\) is the concentration of orthosteric (full) agonist yielding 50% of the response between minimal and maximal receptor activation in the absence of allosteric ligand, \(n\) is a transducer slope factor linking occupancy to response, \(\alpha\) is the binding cooperativity factor (as described above), \(\beta\) is an empirical scaling factor describing the allosteric effect of the modulator on orthosteric agonist signaling efficacy, respectively, and \(\tau_A\) and \(\tau_B\) are operational measure of the ligands’ respective signaling efficacies that incorporate receptor expression levels and efficiency of stimulus-response coupling (Aurelio et al., 2009; Leach et al., 2007). For this analysis, the entire family of curves for a given agonist-modulator combination at each receptor were fitted by constraining the dissociation constant parameter, \(pK_B\), to the value determined in the radioligand binding assays. Equation 2 was used in interaction studies performed between LY2033298 with partial agonists, while equation 3 was used when the modulator was interacted with full agonists, depending on the pathway investigated. This is so because equation 3 is only valid in cases where the orthosteric agonist has high efficacy (\(\tau >> 1\)) such that \(K_A\) is >> [A].
All affinities, potencies, efficacies, and cooperativity parameters were estimated as logarithms (Christopoulos, 1998). Results are expressed as means ± S.E.M. unless otherwise stated. Statistical analyses were by Student’s t-test, or one-way ANOVA followed by Bonferroni’s post-test, as appropriate. Values of p < 0.05 were considered statistically significant.
RESULTS

Rationale behind the choice of M$_2$ mAChR agonists and mutants

A range of mAChR agonists were selected for the study (Fig. 1A), based on their ability to fully or partially activate the M$_2$ mAChR. As high efficacy agonists, we selected acetylcholine (ACh), oxotremorine and oxotremorine M. As lower efficacy agonists, we selected tetramethylammonium (TMA), pilocarpine and xanomeline. We also included the bitopic agonist, McN-A-343, which we recently identified as being able to bridge both the orthosteric site and the allosteric site of the M$_2$ mAChR, (Valant et al., 2008). Fig. 1B shows a snake diagram of the secondary structure of the wild type (WT) M$_2$ mAChR, indicating the residues mutated in the current study. Based on previous work (Gregory et al., 2010), we focused on four key residues, two in TM3, W$_{99}^{3.28}$ and Y$_{104}^{3.33}$, one in the second extracellular loop (E2L), Y$_{177}$, and one in TM6, Y$_{403}^{6.51}$. Both tyrosine residues in the TM3 and TM6, Y$_{3.33}^{3.33}$ and Y$_{6.51}^{6.51}$ respectively, are involved in the binding of the endogenous ligand, ACh, via $\pi$-cation interactions, and were mutated to alanine residues (Heitz et al., 1999; Spalding et al., 2006). Alanine mutation of the W$_{3.28}^{3.28}$ of the mAChRs is known to reduce the affinity of allosteric modulators such as gallamine at the M$_1$ subtype, or LY2033298 at the M$_4$ subtype (Matsui et al., 1995; Leach et al., 2011). Finally, mutation of an aromatic residue in the equivalent position in the E2L has been previously reported to drastically reduce prototypical allosteric modulator affinity, such as gallamine or C$_7$/3-phth at the M$_2$ and M$_4$ subtypes (Valant et al., 2008); this residue is Y$_{177}$ in the M$_2$ mAChR.

LY2033298 binds to the M$_2$ mAChR and displays probe dependence with antagonists

LY2033298 was initially characterized in equilibrium binding assays against the orthosteric antagonist [$^3$H]QNB at the M$_2$ mAChR WT as well as the four mutant receptors (Fig. 2A).
For these experiments, we utilized concentrations of the modulator ranging from 10 nM to 100 μM; we could not go higher due to solubility limitations. Increasing concentrations of LY2033298 caused a significant inhibition of the specific binding of the radioligand, suggesting high negative cooperativity. Application of an allosteric ternary complex model (Eq. 1) to the data provided an estimate of the affinity of LY2033298 for the allosteric site of the unoccupied receptor as well as an estimate of the cooperativity between LY2033298 and the radioligand whose logarithm that was not significantly different from -3 (Table 1), indicative of a negative allosteric interaction that is indistinguishable form a competitive interaction (i.e., \( \alpha' \rightarrow 0 \)). Interestingly, when W99\( ^{3,28} \) was mutated to alanine, the affinity of the modulator was significantly reduced, whereas mutation of Y177A resulted in no change in the specific radioligand binding. This suggested that mutation of this tyrosine in the E2L of the receptor either abrogated the cooperativity between LY2033298 with \( ^3\text{H} \)QNB (\( \alpha' = 0 \)), or substantially reduced the binding affinity of the allosteric ligand. To further probe this latter possibility, experiments were repeated at the WT and Y177A M₂ mAChRs using \( ^3\text{H} \)NMS as the orthosteric radioligand. As shown in Fig. 2B, increasing concentrations of LY2033298 caused a modest but consistent enhancement in the equilibrium binding of \( ^3\text{H} \)NMS at the WT receptor (\( \log \alpha' = 0.50 \pm 0.04 \); i.e., \( \alpha' = 3 \)) , in contrast to the negative allosteric effect observed with \( ^3\text{H} \)QNB. This finding of probe dependence is consistent with the fact that the two radioligands, despite recognizing a similar binding pocket, represent chemically distinct series and thus adopt different orientations within the orthosteric pocket such that they are differentially affected by the conformational change induced by LY2033298. Despite the differences in cooperativity factors for the two antagonists, the estimated dissociation constant for LY2033298 at the unoccupied M₂ mAChR (4.43 ± 0.13; \( n = 3 \)) was not significantly different (\( p < 0.05 \)) from that determined against \( ^3\text{H} \)QNB, as expected. Notably, when the Y177 residue was mutated to alanine, the effect of LY2033298
on \[^3\text{H}\]NMS binding was abolished, suggesting that this residue is indeed vital for the binding of the modulator. Interestingly, the tyrosine mutations within the orthosteric binding site, Y104A\textsuperscript{3.33} and Y403A\textsuperscript{6.51}, drastically modified the allosteric properties of LY2033298 as determined against \[^3\text{H}\]QNB. Mutation of Y104A\textsuperscript{3.33}, which is known to reduce orthosteric agonist and antagonist affinity, also significantly reduced the binding of LY2033298 while switching the cooperativity between LY2033298 and \[^3\text{H}\]QNB from negative to positive. Mutation of Y403A\textsuperscript{6.51}, did not affect the affinity of the modulator for the receptor, but did convert the cooperativity from negative to positive.

To more directly probe the ability of LY2033298 to allosterically modulate orthosteric antagonist binding properties, the effect of the modulator on the rate of association and dissociation of an antagonist was monitored at the M\textsubscript{2} mAChR WT (Fig. 2C and Supp. Figs. 1A and B). We chose \[^3\text{H}\]NMS rather than \[^3\text{H}\]QNB because of the faster rate of dissociation of the former radioligand at the M\textsubscript{2} mAChR. As shown in Fig. 2C, LY2033298 retarded both the association and the dissociation kinetics of \[^3\text{H}\]NMS, however over slightly different concentration ranges such that LY2033298 was more potent at slowing the dissociation (pEC\textsubscript{50} = 5.03 ± 0.06) than the association (pEC\textsubscript{50} = 4.70 ± 0.08) of \[^3\text{H}\]NMS, thus explaining why LY2033298 was a modest potentiator of \[^3\text{H}\]NMS equilibrium binding. In theory, the potency of an allosteric modulator that follows the simple allosteric ternary complex model in affecting the rate of orthosteric radioligand dissociation should be equal to the quotient of the dissociation constant of the modulator for the free receptor and the cooperativity factor, i.e. \(K_B/\alpha\); in contrast, the potency of the modulator for slowing orthosteric radioligand association rate should equal the \(K_B\) only, as it is reflecting the pre-equilibration of the modulator with the free receptor prior to addition of radioligand (Lazareno and Birdsall, 1995; Kostenis and Mohr, 1996). Accordingly, the experimentally-
determined potency of LY2033298 for slowing the association rate of [3H]NMS (pEC$_{50}$ = 4.70) is in good agreement with the pK$_B$ value determined for the modulator from equilibrium binding assays (4.43 - 4.75, depending on which radioligand was used). Similarly, the slightly higher potency for the modulator in slowing [3H]NMS dissociation (5.03) reflects the slight positive cooperativity between the radioligand and the modulator, as the dissociation kinetic experiments quantify the affinity of the modulator for the radioligand-occupied receptor (theoretical value of pK$_B$/α’ predicted from the individual K$_B$ and α’ values from the [3H]NMS equilibrium binding experiments is 4.93).

In contrast, when dissociation kinetic experiments were performed at the M$_2$ mAChR Y177A, no appreciable change of the dissociation rate of [3H]NMS could be observed, supporting the hypothesis that mutation of the tyrosine in the E2L of the M$_2$ mAChR substantially reduces the binding of LY2033298. This latter finding is consistent with similar observations at the M$_4$ mAChR, whereby mutation of F186A (at the equivalent position in the E2L to Y177 at the M$_2$ mAChR) was identified as a key contributor to the binding affinity of LY2033298 for the allosteric site on that receptor (Nawaratne et al., 2010). Taken together, these radioligand binding experiments conclusively show that LY2033298 recognizes an allosteric site on the M$_2$ mAChR, in addition to its well-characterized interaction with the M$_4$ mAChR.

**LY2033298 exhibits binding probe dependence with agonists at the WT M$_2$ mAChR**

To determine the effect of LY2033298 on agonist affinity and cooperativity, interaction studies were performed using [3H]NMS (0.5 nM), LY2033298 and an IC$_{20}$ concentration of agonist at the WT M$_2$ mAChR (Fig. 3; Table 2). Increasing concentrations of LY2033298 positively modulated the affinity of all the mAChR agonists studied, but to markedly
different extents, again indicating the occurrence of probe dependence. The effect of the modulator on ACh affinity was reasonable ($\alpha = 16$), but not as pronounced as we have previously noted at the M$_4$ mAChR ($\alpha$ values ranging up to 60) (Chan et al., 2008; Leach et al., 2011; Leach et al., 2010; Nawaratne et al., 2010; Suratman et al., 2011). Even lower degrees of positive cooperativity were observed with pilocarpine (2.8) and McN-A-343 (8.9), whereas TMA (37) and xanomeline (36) were modulated to a greater extent than ACh. The most dramatic increases in cooperativity were observed when LY2033298 was combined with oxotremorine (390) or oxotremorine M (190).

**LY2033298 differentially modulates mAChR agonist intrinsic efficacy in a ligand- and pathway-dependent manner**

We subsequently investigated the effect of LY2033298 on M$_2$ mAChR signaling at two different pathways, $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding to activated G$\alpha$ proteins and pERK1/2. $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding was chosen as a proximal measure of receptor activation, while the pERK1/2 assay was chosen because it measures a downstream response that is also a point of convergence of multiple cellular pathways, some of them potentially G protein-independent. If the system behaved according to a simple two-state model and the two pathways are sequentially linked to one another, then we would expect to see a correlation between the direction and degree of modulation of a given agonist at both the proximal and distal pathways (Keov et al., 2011). In contrast, if the allosteric modulator imposes bias on the signaling of the agonist, then a divergence between the effect on $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding and pERK1/2 may be seen.

The interaction between LY2033298 and each of the agonists at the WT M$_2$ mAChR is shown in Fig. 4 (pERK1/2) and Fig. 5 ($[^{35}\text{S}]\text{GTP}\gamma\text{S}$), while Fig. 6 and Table 3 summarize the functional cooperativity estimates ($\alpha\beta$ values) for each agonist/pathway obtained from
application of equations 2 (for the partial agonists) and 3 (for the full agonists) to the data. From these experiments, it could be seen that LY2033298 on its own was able to mediate a degree of direct receptor activation, indicative of allosteric agonism; this was most noticeable in the pERK1/2 experiments (Fig. 4), presumably because this pathway is more downstream of receptor activation than the $[^{35}\text{S}]\text{GTP}_{\gamma}\text{S}$ assay. More importantly, it was also evident that LY2033298 exhibited markedly different degrees of not only positive, but also negative, functional cooperativity depending on the agonist used; in contrast, only different degrees of positive cooperativity were noted on agonist binding properties (Table 2; Fig. 3). The most striking effects were observed with pilocarpine and xanomeline, which showed a reduction of maximal agonist response in the presence of increasing concentrations of LY2033298, despite the fact that the modulator, on its own, increased the activity of the receptor, i.e., behaved as an allosteric agonist (Figs. 4 and 5). This finding indicates that the conformation of the receptor that binds LY2033298 and either pilocarpine or xanomeline is clearly distinct from the conformation(s) engendered by any of the ligands on their own, as the ternary complexes formed yield inactive receptor states, whereas the binary ligand-receptor complexes are active.

Although the reversals in efficacy of xanomeline and pilocarpine in the presence of LY2033298 were the most obvious indicators of biased receptor states, it was also evident that more subtle differences existed in the profiles of modulation of the other agonists. For instance, ACh experienced greater potentiation at the level of the $[^{35}\text{S}]\text{GTP}_{\gamma}\text{S}$ assay than pERK1/2, whereas oxotremorine, TMA and McN-A-343 showed the reverse preferences (Fig. 6A). Because the modulation of agonist affinity was positive in all instances, the variations in the functional cooperativity between agonists across the two pathways suggest that the underlying modulation of agonist efficacy may be negative for multiple agonists.
beyond the obvious case of pilocarpine and McN-A-343. This is illustrated more clearly in Figure 6B, where the cooperativity factors determined in the binding assays (α values) were subtracted from the functional αβ factors to yield estimates of β for each agonist at each pathway.

**Mutations in the orthosteric site of M₂ mAChR affect functional cooperativity factors.**

The functional interaction studies were subsequently extended to the mutant receptors, and the estimates of cooperativity obtained are shown in Table 3 and Fig. 7; Supplementary Figs 2-7 show the complete concentration-response data for these experiments. Not surprisingly, no effect of LY2033298 was noted at the M₂ mAChR Y177A receptor, consistent with our hypothesis that the modulator does not bind appreciably to this E2L mutant. The main finding at the W99A mutant was the selective reduction in the cooperativity between McN-A-343 and LY2033298. Interestingly, both Y104A and Y403A mutations caused marked reductions in agonist signaling efficacy that could be uniformly rescued by LY2033298 at the latter mutant (Fig. 7C), but only for the most efficacious agonists at the former (Fig. 7B). Moreover, at these mutant receptors the pERK1/2 response was always potentiated to a greater extent than the [³⁵S]GTPγS response; the mutant receptors essentially behave according to a classic two-state system (Keov et al., 2011), with the biased modulation evident at the WT receptor being lost at these mutants.
DISCUSSION

There are three major findings from this study. First, the recently-described “selective” M₄ mAChR modulator, LY2033298, interacts with the M₂ mAChR via a site that shares similarities with the common allosteric site in mAChRs. This highlights the fact that allosteric modulators can achieve receptor targeting not only by binding to less-conserved sites, but also via subtype-selective cooperativity upon interaction with potentially conserved allosteric sites. A second finding is the difference in the allosteric effect exerted by LY2033298 on various agonists and antagonists of the M₂ mAChR. This probe dependence has major implications for drug discovery, because the identification and subsequent classification of an allosteric ligand will depend on the orthosteric ligand that is used. Moreover, the potential clinical utility of combining an allosteric ligand with an existing orthosteric medicine for a given GPCR target must also take into account the possibility of probe dependent off-target effects at other GPCRs. Finally, a third finding was the differential effects of receptor mutations on the transmission of cooperativity with various M₂ mAChR agonists, suggesting that some of these residues play important roles in the ability of the M₂ mAChR to transition between multiple active states.

Previous studies have revealed that the mAChRs possess at least one allosteric site located extracellularly to the orthosteric site (Wess, 2005; Gregory et al., 2007). This pocket is referred to as the “common” allosteric site, because prototypical modulators, such as gallamine, alcuronium and C₇/₃-phth, interact with all five mAChR subtypes, albeit with different degrees of affinity / selectivity (Christopoulos et al., 1999; Gregory et al., 2007). In addition to demonstrating conclusively that LY2033298 interacts with the M₂ mAChR, our study has revealed that the binding of the modulator is very sensitive to mutation of Y177 within the E2L, a residue known to be important for the binding of prototypical modulators.
(Avlani et al., 2007; Valant et al., 2008). Given that mutation of F186 in the equivalent position of the M₄ mAChR E2L abolishes the binding of LY2033298 to that receptor (Nawaratne et al., 2010), as well the fact that LY2033298 displays competitive behavior against the prototypical modulator, C₇/3-phth, at the M₄ mAChR (Leach et al., 2010), it is reasonable to speculate that the interaction of LY2033298 with the M₂ mAChR also involves, at least in part, binding to the site utilized by other well-characterized mAChR modulators. We recently identified another conserved residue, W₃.₂₈, as contributing to the binding of LY033298 at the M₄ mAChR, and proposed that this residue sits at the interface between orthosteric and allosteric sites (Leach et al., 2011). In our current study, mutation of W₃.₂₈ also reduced the affinity of LY2033298 for the M₂ mAChR, but to a lesser extent than at the M₄ mAChR. On the one hand, this supports the hypothesis that LY2033298 interacts with a common allosteric pocket at these two mAChRs, but on the other hand it suggests that the binding pose is sufficiently different at the two receptors such that not all mutations will affect the modulator to the same extent across subtypes. It is possible that this is a more general phenomenon warranting further study across other GPCRs.

The expectation that LY2033298 adopts a different orientation in the M₂ mAChR relative to the M₄ mAChR is convincingly demonstrated by the differences in the probe dependence between the modulator and orthosteric ligands. Whereas the positive cooperativity between ACh and LY2033298 is most marked at the M₄ mAChR, it is lower at the M₂ mAChR, and essentially neutral at the other mAChR subtypes (Chan et al., 2008). Based on these observations, we conclude that the selectivity ascribed to the modulator arises predominantly as a consequence of differential cooperativity with ACh across mAChRs. This is also in accord with our recent study of species differences in the effects of LY2033298 at the M₄ mAChR; the lower potency of the modulator at the rodent M₄ mAChR relative to the human...
was again due to differences in cooperativity, not affinity, between species (Suratman et al., 2011). Interestingly, the interaction between LY2033298 and antagonists at the M2 mAChR was also different to that noted at the M4 mAChR. Whereas the interaction with [3H]NMS is positive at the M2 mAChR, it is weakly negative at the M4 mAChR (Leach et al., 2010). For [3H]QNB, the interaction is neutral at the M4 (Leach et al., 2010; 2011) but negative at the M2 mAChR.

The study of probe-dependence is important for drug discovery, being particularly pertinent to situations where the endogenous agonist cannot be used for assessing the activity of putative allosteric ligands, perhaps due to metabolic instability or, for orphan GPCRs, where the endogenous agonist is not known; in both instances, surrogate orthosteric agonists (or antagonists) are required. It is also relevant for GPCRs that possess more than one endogenous agonist. The implications of our study are that an allosteric effect may be missed, if the probe dependence leads to neutral cooperativity, or misinterpreted, even across multiple endogenous agonists for a single GPCR (Koole et al., 2010). For the mAChRs, it is common to see brain penetrant analogs of ACh, such as oxotremorine, used as surrogate probes to provide exogenous tone for in vivo studies (e.g., Chan et al. (2008); Leach et al., (2010)). However, the fact that LY2033298 displays substantially higher positive cooperativity with oxotremorine than ACh means that in vivo studies ostensibly focused on M4 mAChRs may inadvertently recruit M2 mAChRs upon co-administration of compounds such as LY2033298 and oxotremorine, thus potentially confounding the interpretation of the experimental results. Indeed, this is likely why the effects of co-administration of these two compounds on the conditioned avoidance response in M4 mAChR knockout mice, although markedly attenuated, are not completely abolished (Leach et al., 2010). Finally, the effect of LY2033298 on compounds such as pilocarpine and xanomeline is particularly noteworthy,
because in this situation the cooperativity is so highly negative that both agonists are essentially converted into antagonists in the presence of modulator. The finding that their binding is actually improved while their signaling efficacy is concomitantly abolished is reminiscent of the effects of the allosteric modulator, Org27569, at the CB₁ cannabinoid receptor (Price et al., 2005), suggesting that this phenomenon may be more common than appreciated. Xanomeline has already shown clinical efficacy in improving cognitive deficits in schizophrenia (Shekhar et al., 2008), but combination with LY2033298, which also demonstrates preclinical efficacy in a variety of antipsychotic models, may not prove useful due to the potential for introducing off-target antagonistic effects at the M₂ mAChR.

Within a simple two-state receptor model, it is expected that the degree of allosteric modulation would correlate with the intrinsic efficacy of the ligands and the degree of stimulus-response amplification (Hall, 2000; Keov et al., 2011). If this were the case, then we would have expected a greater degree of allosteric potentiation of ERK1/2 activity over [³⁵S]GTPγS binding at the WT M₂ mAChR, which was not observed. The fact that the probe dependence was, instead, characterized by both positive and negative modulation in an agonist- and pathway-dependent manner is consistent with the notion that GPCRs can adopt multiple biologically active states that can be differentially stabilized by orthosteric and allosteric ligands (Leach et al., 2007; Keov et al., 2011). Because for most diseases there is currently no definitive link between a given cellular pathway and a desired therapeutic outcome, allosteric modulator screening should be as broad as possible, and ideally benchmarked iteratively against appropriate in vivo disease models during the drug candidate selection process. This will increase the likelihood of correlating in vitro “fingerprints” (e.g., positive modulation of G protein activation, negative modulation of ERK1/2 phosphorylation etc.) with in vivo efficacy.
Finally, it was interesting to note the effects of mutations on the bias imposed by LY2033298. Both Y104A$^{3.33}$ and (especially) Y403A$^{6.51}$ were sensitive to functional rescue by the allosteric modulator, but in a manner that was consistent with a simple two-state mechanism, i.e., in all instances where functional modulation was observed, the ERK1/2 pathway was potentiated to a greater extent than the more proximal [$^{35}$S]GTPγS response. It is possible that the two amino acids participate in a key network of interactions that facilitate the ability of the receptor to transition between multiple active states, perhaps in a sequential fashion as proposed for other biogenic amine GPCRs (Liapakis et al., 2004). Disruption of the network as a consequence of mutation may thus limit the transition to fewer, but more abundant, substates.

In conclusion, we have identified LY2033298 as a robust allosteric modulator of the M$_2$ mAChR, in addition to the M$_4$ mAChR. Key novel findings arising from this work include the fact that allosteric selectivity between GPCR subtypes can arise due to differences in cooperativity with the endogenous agonist, rather than differences in allosteric binding pockets; that opposite effects can be exerted by an allosteric modulator on agonist affinity versus agonist efficacy; that this profile of effects need not be retained when switching agonists or signaling pathways. These examples of probe dependence also have broader implications for the detection, classification and validation of allosteric modulators of other GPCRs, and highlight how investigations of the phenomenon should be incorporated into allosteric modulator discovery efforts.
ACKNOWLEDGEMENTS

We would like to thank Drs. Michael Crouch and Ron Osmond (TGR Biosciences) for the generous donation of AlphaScreen SureFire phospho-ERK1/2 reagents.

FIGURE LEGENDS

Figure 1. Ligands and mutants investigated in this study. (A) mAChR agonists used in this study. (B) Snake diagram of the M2 mAChR highlighting residues mutated in alanine, and agonist structures of ligands used in this study.

Figure 2. LY2033298 interacts allosterically at the M2 mAChR. (A) Effect of LY2033298 on the equilibrium binding of [3H]QNB at the WT and four mutant receptors. (B) Effect of LY2033298 on the equilibrium binding of [3H]NMS at the wild type (WT) the Y177A M2 mAChR. (C) Concentration-dependent slowing by LY2033298 of the dissociation at the WT and Y177A M2 mAChR, and apparent association rate of [3H]NMS at the WT and M2 mAChR. Kinetic rate constants were determined in the presence of increasing concentrations of LY2033298 at three times points and normalized as a percentage of the rate constants determined in the absence of modulator. In all instances, data points represent the mean ± S.E.M of three experiments performed in duplicate.

Figure 3. LY2033298 differentially modulates agonist binding at the M2 mAChR. The competition between 0.5 nM [3H]NMS and an IC20 concentration of agonist was determined in presence of increasing concentrations of LY2033298. The curves drawn through the points represent the best global fit of an allosteric ternary complex model (Equation 1) to each pair of datasets (ACh competition of [3H]QNB binding and the IC20 concentration of ACh in the presence of LY2033298). Data points represent the mean ± S.E.M of three experiments performed in duplicate.
Figure 4. **LY2033298 mediates both positive and negative allosteric effects on M₂ mAChR-mediated ERK1/2 phosphorylation in an agonist-dependent manner.** Concentration-response curves to the indicated agonist were generated in the absence or presence of increasing concentrations of LY2033298. Data points represent the mean ± S.E.M of three experiments performed in duplicate. The curves drawn through the points represent the best global fit of an operational model of allosterism (Equation 2 for pilocarpine, xanomeline and McN-A-343 or Equation 3 for ACh, oxotremorine, oxotremorine-M and TMA), as described in the Methods and Results.

Figure 5. **LY2033298 mediates both positive and negative allosteric effects on M₂ mAChR-mediated [35S]GTPγS binding in an agonist-dependent manner.** The curves drawn through the points represent the best global fit of an operational model of allosterism (Equation 2 for TMA, pilocarpine, xanomeline and McN-A-343 or Equation 3 for ACh, oxotremorine and oxotremorine-M). All other details as for Figure 4.

Figure 6. **LY2033298 displays divergent cooperativity estimates with different agonists at the wild type M₂ mAChR.** (A) Functional cooperativity estimates (composite αβ values) derived from analysis of the data in Figures 4 and 5. Values are also shown in Table 3. (B) Individual estimates of α and β values calculated by subtraction of the cooperativity factors determined in the radioligand binding studies from the composite estimates determined from the functional assays.

SUPPLEMENTARY DATA

Molecular Pharmacology:

Probe-dependence in the allosteric modulation of a G protein-coupled receptor: Implications for detection and validation of allosteric ligand effects

Celine Valant, Christian C. Felder, Patrick M. Sexton and Arthur Christopoulos

Drug Discovery Biology & Department of Pharmacology, Monash Institute of Pharmaceutical Sciences, Monash University, Parkville, VIC, Australia (CV, PMS, AC); Neuroscience Division, Eli Lilly & Co., Indianapolis, IN, USA, (CCF)
Supplementary Figure 1. Concentration-effect relationships for LY2033298 on orthosteric radioligand kinetics. Effect of the modulator on (A) the apparent association rate of [³H]NMS at the WT M₂ mAChR, (B) the dissociation rate of [³H]NMS at the WT M₂ mAChR or (C) the dissociation rate of [³H]NMS at the Y177A M₂ mAChR. Data points represent the mean ± S.E.M of three experiments performed in duplicate.

Supplementary Figure 2. Effects of LY2033298 on ERK1/2 phosphorylation at the W99³.28A mutant M₂ mAChR. Concentration-response curves to the indicated agonist were generated in the absence or presence of increasing concentrations of LY2033298. Data points represent the mean ± S.E.M of three experiments performed in duplicate. The curves drawn through the points represent the best global fit of an operational model of allosterism (Equation 2 or 3), as described in the Methods and Results.

Supplementary Figure 3. Effects of LY2033298 on [³⁵S]GTPγS binding to activated G proteins at the W99³.28A mutant M₂ mAChR. Concentration-response curves to the indicated agonist were generated in the absence or presence of increasing concentrations of LY2033298. Data points represent the mean ± S.E.M of three experiments performed in duplicate. The curves drawn through the points represent the best global fit of an operational model of allosterism.

Supplementary Figure 4. Effects of LY2033298 on ERK1/2 phosphorylation at the Y104³.33A mutant M₂ mAChR. All other details as for Supplementary Figure 2.
Supplementary Figure 5. Effects of LY2033298 on $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding to activated G proteins at the Y104$^{3.33}$A mutant M$_2$ mAChR. All other details as for Supplementary Figure 3.

Supplementary Figure 6. Effects of LY2033298 on ERK1/2 phosphorylation at the Y403$^{6.51}$A mutant M$_2$ mAChR. All other details as for Supplementary Figure 2.

Supplementary Figure 7. Effects of LY2033298 on $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding to activated G proteins at the Y403$^{6.51}$A mutant M$_2$ mAChR. All other details as for Supplementary Figure 3.
