Abstract

Regulator of G protein signaling 2 (RGS2) plays a role in reducing vascular contraction and promoting relaxation due to its GTPase accelerating protein activity toward Gαq. Previously, we identified 4 human loss-of-function (LOF) mutations in RGS2 (Q2L, D40Y, R44H and R188H). This study aimed to investigate whether those RGS2 LOF mutations disrupt the ability of RGS2 to regulate vascular reactivity.

Isolated mesenteric arteries (MAs) from RGS2−/− mice showed an elevated contractile response to 5 nM angiotensin II and a loss of acetylcholine (ACh)-mediated vasodilation. Reintroduction of a wild-type RGS2-GFP plasmid into RGS2−/− MAs suppressed the vasoconstrictor response to angiotensin II. RGS2 LOF mutants failed to suppress the angiotensin II constriction response compared to RGS2 WT. In contrast, ACh-mediated vasoconstriction was restored by expression of RGS2 WT, D40Y and R44H but not by RGS2 Q2L or R188H. Phosphorylation of RGS2 D40Y and R44H by protein kinase G (PKG) may explain their maintained function to support relaxation in MAs. This is supported by phosphomimetic mutants and suppression of vasorelaxation mediated by RGS2 D40Y by a PKG inhibitor.

These results demonstrate that RGS2 attenuates vasoconstriction in MAs and that RGS2 LOF mutations cannot carry out this effect. Among them, the Q2L and R188H mutants supported less relaxation to acetylcholine while relaxation mediated by the D40Y and R44H mutant proteins was equal to that with WT protein. Phosphorylation of RGS2 by PKG appears to contribute to this vasorelaxation. These results provide insights for precision medicine targeting the rare individuals carrying these RGS2 mutations.
Human RGS2 mutations alter vascular reactivity

Significance statement

The Regulator of G protein Signaling protein 2 (RGS2) has been implicated in control of blood pressure; rare mutations in the RGS2 gene have been identified in large scale human gene sequencing studies. Four human mutations in RGS2 that cause loss-of-function (LOF) in cell-based assays were examined in isolated mouse arteries for effects on both vasoconstriction and vasodilation. All mutants showed the expected LOF effects in suppressing vasoconstriction. Surprisingly, the D40Y and R44H mutant RGS2 showed normal control of vasodilation. We propose that this is due to rescue of the mislocalization phenotype of these two mutants by NO-mediated/PKG-dependent phosphorylation. These mechanisms may guide drug discovery or drug repurposing effort for hypertension by enhancing RGS2 function.
Human RGS2 mutations alter vascular reactivity

Introduction

G protein-mediated signaling is critical for the regulation of cardiovascular function, including heart rate, cell growth, and vascular tone. Blockers of GPCR signaling (angiotensin receptor and beta and alpha adrenergic receptor blockers) are among the best therapies for hypertension and heart failure. Regulator of G protein Signaling (RGS) proteins accelerate the rate of GTP hydrolysis by active Gαi/o and Gαq subunits, thereby reducing the amplitude and duration of GPCR/G protein signaling. Among more than 20 RGS proteins, RGS2 is highly expressed in vascular smooth muscle cells, where it is regulated by nitric oxide and controls vascular constriction and relaxation (Sun et al., 2005b; Tang et al., 2003a).

Biochemically, RGS2 negatively regulates Gαq, which transduces signals from a variety of vasoconstrictors. Consistent with a role in vascular control, RGS2 knockout mice are hypertensive (Heximer et al., 2003) and hypertensive human patients had reduced RGS2 mRNA in peripheral blood mononuclear cells compared to controls (Semplicini et al., 2006). Further, hypertensive patients were more likely to have the single nucleotide polymorphism (SNP) C1114G in the 3’ untranslated region of the RGS2 gene which correlated with lower RGS2 protein expression in cultured fibroblasts isolated from skin biopsy (Semplicini et al., 2006). Several rare coding SNPs were found in a Japanese hypertensive cohort at a frequency higher than normotensive controls but the sample size was too small to reach statistical significance (Yang et al., 2005). Subsequent study confirmed loss of function (LOF) of these SNPs in vitro and defined mechanisms (Bodenstein et al., 2007; Gu et al., 2008b). We recently identified four LOF mutations in human RGS2 (Phan et al., 2017) from a set of 16 variants of unknown significance (VUS) found in the Genome Aggregation Database (Lek et al., 2016). Though biochemically characterized, the functional consequences of these mutations in the complex milieu of vascular tissue are unknown.
Human RGS2 mutations alter vascular reactivity

Here, we utilized an ex vivo method in mesenteric arteries (MAs) to examine how these mutations affect vascular reactivity. We hypothesized that the LOF phenotype of RGS2 mutants identified in cell-based assay would have LOF physiological consequence in the MAs.

Materials and methods

Ethical approval

All experimental procedures were approved by the Michigan State University Animal Care and Use Committee and were performed in accordance with the Guide for the Care and Use of Laboratory Animals established by the National Institutes of Health.

Animals

C57Bl/6 mice with wild type and RGS2\(^{-/-}\) genotypes were obtained from Dr. Kendall Blumer at Washington University St. Louis (Osei-Owusu et al., 2015). Mice were provided access to food and water ad libitum in the MSU animal facility on a 12h light/dark cycle. All of the experiments were performed using 3–5 month old male mice. Mice were anesthetized by isoflurane, followed by removal of the mesentery and then euthanized by cervical dislocation.

Materials

Rp-8-pCPT-cGMPS (Item 18445, CAS 208445-07-2) was purchased from Cayman Chemical. Angiotensin II (AngII) (A9525), phenylephrine (PE) (P6126), acetylcholine (ACh) (A6625) were purchased from Sigma – Aldrich.

Pressure myography

Mesenteric arteries (MAs) were isolated free of adipose and connective tissue in a physiological salt solution (PSS) containing (in mM) 140 NaCl, 5 KCl, 1 MgCl\(_2\)·6H\(_2\)O, 10 HEPES, 10 dextrose, pH 7.4 at 4 °C. MAs were mounted between two glass micropipettes in a custom-made cannulation
Human RGS2 mutations alter vascular reactivity

chamber and were visualized on the stage of an inverted microscope (Zeiss Axiovert 35) as previously described (Diaz-Otero et al., 2016). Arteries were pressurized and then equilibrated for 60 min in PSS containing (in mM) 140 NaCl, 5 KCl, 1.8 CaCl₂·2H₂O, 1 MgCl₂·6H₂O, 10 HEPES, and 10 dextrose at 37°C. The baseline internal diameter and changes of diameter in response to vasoactive substances were recorded at 80 mm Hg and 37 °C using MyoVIEW II 2.0 software (Danish Myo Technology, Aarhus, Denmark). All MAs were challenged with 3µM PE to test their reactivity before experiments were performed. MAs that did not contract upon PE addition were discarded. Data are expressed as percentage of buffer baseline.

Wire myography

Methods were described previously (Russell and Watts, 2000) with modification. Aortas from RGS2+/+ and RGS2−/− mice were isolated free of fat and connective tissue and cut into rings (2-3 mm in length). The aortic rings were mounted on two L-shaped stainless-steel wires inserted into the lumen and immersed in muscle baths filled with warm, aerated PSS containing (in mM) 130 NaCl, 4.7 mM KCl, 1.18 KH₂PO₄, 1.17 MgSO₄·7H₂O, 1.6 CaCl₂·2H₂O, 14.9 NaHCO₃, 5.5 dextrose, and 0.03 CaNa₂EDTA). One end of the preparation was attached to a stainless steel rod, the other was attached to a force transducer (FT03; Grass Instruments, Quincy, MA). The basal tension of the aortic ring was maintained at 0.5 g. Changes in isometric force after adding PE in a cumulative manner were recorded on a Grass polygraph (Grass Instruments).

Reversible permeabilization

Reversible permeabilization of isolated MAs to introduce RGS2 plasmids to the MAs was achieved by a modification of previous methods (Lesh et al., 1995; Welsh et al., 2002). Briefly, MAs from RGS2−/− mice were loaded with RGS2-GFP constructs by sequential incubation in the following solutions (in mM): (1) 10 EGTA, 120 KCl, 5 Na₂ATP, 2 MgCl₂, 20 TES (pH 6.8; 120
**Human RGS2 mutations alter vascular reactivity**

MOL # 116822

min, 4 °C); and (2) 0.1 EGTA, 120 KCl, 5 Na$_2$ATP, 2 MgCl$_2$, 20 TES and 1 µg/ml of RGS2-GFP plasmids (pH 6.8; overnight, 4 °C). Subsequently, arteries were transferred to following solutions (in mM): (3) 0.1 EGTA, 120 KCl, 5 Na$_2$ATP, 10 MgCl$_2$, 20 TES (pH 6.8; 30 min, 4 °C); (4) 140 NaCl, 5 KCl, 10 MgCl$_2$, 5.6 glucose, and 2 MOPS (3-[N-morpholino] propane-sulfonic acid) (pH 7.1, 30 min, room temperature), then [Ca$^{2+}$] was gradually increased from 0.001 to 0.01 to 0.1 to 1.6 to 2.4 mM every 10 min by adding CaCl$_2$ to solution 4. Arteries were then incubated in DMEM/F-12 culture medium (Cat. 11039021, Gibco) supplemented with 50 U/ml penicillin, and 50 mg/ml streptomycin and maintained at 37 °C, 5% CO$_2$ in an incubator. The MAs expressing RGS2-GFP was used for myography 24-48 hours after being transferred to culture medium.

**Immunofluorescence**

After reversible permeabilization, MAs were fixed in 4% paraformaldehyde for 24 hours and rinsed with phosphate buffer (PB), pH 7.2. The arteries were permeabilized in DMSO 100% for 10 min, then incubated in blocking buffer - PB buffer containing 4% donkey serum (Sigma-Aldrich, St. Louis, MO, Cat # D9663, Lot # SLBQ9773V) for 30 min and then with rabbit anti-GFP antibody (Life Technologies, Carlsbad, CA, Cat. A6455) at 1:500 dilution at 4°C overnight. The arteries were then rinsed with 0.2% Triton X-100 in PBS and incubated in Cy3-anti-rabbit secondary antibody (Jackson ImmunoResearch, West Grove, PA, Code # 711-165-152, Lot # 131748) at 1:300 dilution at room temperature. The arteries were mounted using ProLong™ Gold Antifade Mountant with DAPI (Life Technologies, Carlsbad, CA, Cat. P36941) and visualized using a 40x objective in an Olympus FluoView 1000 laser scanning confocal microscope.

**Cell culture and transfection**

Cell lines were maintained in a humidified incubator at 37°C with 5% CO$_2$. Human embryonic kidney (HEK)-293 cells and Chinese hamster ovary (CHO-K1) cells (ATCC, Manassas, VA) were
Human RGS2 mutations alter vascular reactivity

maintained in Dulbecco’s modified Eagle’s medium (DMEM; GIBCO, Carlsbad, CA) and F-12 nutrient mixture (GIBCO, Carlsbad, CA), respectively, supplemented with 10% fetal bovine serum (FBS), 100 U/ml penicillin, and 100 mg/ml streptomycin. X-tremeGENE HP DNA Transfection Reagent (Roche Life Sciences) and DNA-In® CHO (MTI-GlobalStem, Gaithersburg, MD) were used to transfect HEK-293 cells and CHO-K1 cells according to the manufacturers’ recommended protocols. Transfection mixes were prepared in antibiotic-free Opti-MEM (GIBCO, Carlsbad, CA). Experiments were run 24-48 hours after transfection.

Confocal microscopy

HEK293 cells were seeded onto collagen-coated 35 mm glass-bottom Petri dishes (MatTek Corporation, Ashland, MA) and transfected with RGS2-GFP plasmid constructs along with plasmid DNA encoding GαqQ209L or pcDNA3.1 as control. An Olympus FluoView 1000 laser scanning confocal microscope with a 60x oil immersion objective using 488 nm excitation and 505–530 nm emission wavelengths for GFP was used for live cell imaging. This experiment was done 24 hours post-transfection. Representative images of at least 80 live cells per condition from 3 independent experiments were acquired. The line scan analysis function in ImageJ (Schneider et al., 2012) was used to perform densitometric quantitation of protein expression.

Ca²⁺ mobilization assay

CHO cells were seeded into black, flat, clear bottom 384-well plates (Greiner Bio-one, Kremsmünster, Austria) 24 hours post-transfection. Cells were allowed to attach overnight. After removing the media, cells were loaded with 1X Fluo-4 NW (Molecular Probes, Eugene, OR) in a loading buffer containing Hank’s basal saline solution (HBSS), 20 mM HEPES, pH 7.4 supplemented with 2.5 μM probenecid. The cell plates were incubated for 30 min at 37°C, followed by 30 min at room temperature. The Fluo-4 NW was removed and loading buffer was
Human RGS2 mutations alter vascular reactivity

added at 20 µl/well to the cell plate. A range of concentrations of angiotensin II (Sigma, Cat. A9525) at 2x the final concentration was freshly prepared in loading buffer supplemented with 0.1% BSA in a ligand plate for automated injection into the wells at 20 µl/well by a FDSS/µCell kinetic fluorescence plate reader (Hamamatsu Photonics, Japan). Assay plates were placed in the plate reader and changes of intracellular free calcium in response to the receptor activation were measured.

Statistical analyses

Data are presented as means ± SE. Vessel diameter data were analyzed by Student's t-test or two-way analysis of variance (ANOVA) followed by the indicated multiple-comparisons test. All statistical analyses were performed using GraphPad Prism 6.0 software (GraphPad, San Diego, CA). Statistical significance was denoted by P < 0.05, or as indicated in figure legend.
Human RGS2 mutations alter vascular reactivity

Results

RGS2 deficiency enhances vascular contractility to phenylephrine and angiotensin II and causes impairment of acetylcholine-mediated vasorelaxation

Vascular responses of RGS2-deficient arteries to vasoconstrictors and vasodilators have been extensively studied in different vascular beds including aorta, mesenteric artery, renal interlobar and uterine artery (Hercule et al., 2007; Jie et al., 2016; Osei-Owusu et al., 2012; Tang et al., 2003b). Here we assessed the response of MA and aorta to PE, AngII and ACh with the goals of 1) validating the effect of RGS2 deficiency on vascular reactivity and 2) optimizing experimental conditions for studies of RGS2 mutant proteins in the context of vascular tissue. Second-order MAs and rings from the thoracic aorta from male RGS2+/+ and RGS2-/- mice were used to determine how RGS2 protein affects vascular reactivity to different vasoactive substances. Phenylephrine, which activates the Gαq-coupled α1 adrenergic receptor, caused a concentration-dependent contraction in RGS2+/+ MAs and aorta; this response was significantly augmented in RGS2−/− aortic rings in wire myography (Fig. 1B) but not in pressurized MAs from RGS2−/− mice (Fig. 1A). The MAs isolated from RGS2−/− mice did show increased responsiveness to 5 nM AngII (Fig. 1C, 28 ± 1.8% contraction in RGS2−/− vs 10 ± 2.6% in RGS2+/+, p < 0.01, Student t-test, Fig. S1A). Also, the maximum of ACh-mediated vasodilation in RGS2−/− MA pre-constricted with 3 μM PE was markedly impaired (Fig. 1D, 48.6 ± 8.4% relaxation in RGS2−/− vs 92.7 ± 6.2% relaxation in RGS2+/+, ** p < 0.01, **** p < 0.0001, two-way ANOVA with Sidak post-test). We chose to focus on testing reactivity of MAs expressing RGS2 mutants to AngII and ACh in subsequent experiments because MAs contribute to vascular resistance which determines arterial blood pressure (Christensen and Mulvany, 1993).

Expression of RGS2-GFP in cultured RGS2−/− MAs
**Human RGS2 mutations alter vascular reactivity**

Using reversible permeabilization to deliver plasmids into intact arteries, we were able to express RGS2-GFP constructs in MAs. Immunofluorescent staining of GFP showed that RGS2-GFP is present in the MA between 48-72 hours after reversible permeabilization but absent with a pcDNA3.1 transfection control (Fig. 2A). The staining also showed that the Q2L-GFP appeared to have lower intensity compared to WT and other mutant RGS2 in the MAs which aligned with the low protein level of the Q2L mutant in CHO cells (Phan et al., 2017). Further characterization was done by performing z-stack imaging by confocal microscopy. RGS2-GFP was expressed in the vascular smooth muscle cell layer and virtually absent RGS2-GFP in the endothelial cell layer (Fig. 2B), based on the depth in the z-stack and morphology of cell nuclei - elongated nuclei in VSMCs and round nuclei in endothelial cells (Luo et al., 2016).

**RGS2 LOF mutations fail to suppress AngII-induced vasoconstriction**

To examine the effect of RGS2 mutants in regulating vasoconstriction, we expressed plasmid constructs encoding RGS2 WT and mutants in RGS2−/− MAs by reversible permeabilization versus empty vector as control. For these experiments, we used a higher concentration of AngII for cultured MAs (50 nM instead of 5 nM in freshly isolated arteries). In pilot studies with transfected RGS2 KO MAs, 30 nM AngII gave only a small contractile response while 50 nM gave a response similar that that elicited by 5 nM and 50 nM in untransfected MAs (Fig. S1B). The 50 nM AngII provided sufficient significant vasoconstriction to be able to observe effects of RGS2 in transfected arteries. This is potentially due to impaired receptor function after reversible permeabilization. MAs expressing empty vector or RGS2−/− MAs without RGS2 transfection, showed 34.3 ± 4.7% (Fig. 3A) and 30.0 ± 3.1% (Fig. 3B) contraction relative to baseline, respectively. Expression of RGS2 WT was able to suppress contraction in two independent experiments. In MAs expressing RGS2 WT, AngII caused a reduction in arterial diameter of only 4.2 ± 1.3% (p < 0.01, one-way
Human RGS2 mutations alter vascular reactivity

ANOVA, Dunnett post-test, Fig. 3A) and 7.2 ± 2.6% (p < 0.05, one-way ANOVA, Dunnett post-test, Fig. 3B). Two mutants identified in our previous work as having normal function, RGS2 M5V and A99G (Phan et al., 2017), resulted in a similar level of vascular contraction to RGS2 WT (6.8 ± 3.6% and 10.9 ± 4.2%, respectively, Fig. 3B). The RGS2 Q2L mutant gave reduced suppression of contraction compared to RGS WT (18.8 ± 6.6% constriction versus 4.2 ± 1.3%), however, the difference was not statistically significant (p = 0.09) (Fig. 3A). Arteries expressing RGS2 D40Y, R44H, and R188H mutants showed a significantly elevated contractile response to 50 nM AngII stimulation, 28.3 ± 7.7%, 25.7 ± 8.7% and 29.8 ± 5.5%, respectively, compared to arteries expressing RGS2 WT 4.2 ± 1.3% (p < 0.05, one-way ANOVA, Dunnett post-test) (Fig. 3).

RGS2 LOF mutations differentially affect acetylcholine-evoked vasodilation

Because freshly isolated RGS2−/− MAs show reduced relaxation to ACh, LOF mutations of RGS2 may behave similarly. To probe the function of these mutants in mediating ACh-induced vascular relaxation, we measured ACh-evoked vasodilation of MAs expressing WT and mutant RGS2. Using MAs pre-constricted with PE (3 µM), we found that cultured RGS2-deficient MA (transfected with empty vector) showed a maximal relaxation of 52.8 ± 14.3% (Fig. 4). This is similar to the response of freshly isolated RGS2−/− MAs (48.6 ± 8.4%, Fig. 1C) and much less than that of arteries expressing WT RGS2 (99.6 ± 5.5%, p = 0.0001, two-way ANOVA with Dunnett post-test, Fig. 4). Among the four LOF mutants, we found that ACh-mediated relaxation with the RGS2 Q2L and R188H mutants was significantly impaired compared to RGS2 WT (Q2L 75 ± 7%, p < 0.05; R188H 63.8 ± 14.3%, p < 0.001, Dunnett post-test, Fig. 4A). Arteries expressing the D40Y and R44H mutant RGS2, however, showed an equivalent relaxation response to those with RGS2 WT (D40Y 98.4 ± 12.3%, R44H 93.98 ± 4.8%, Fig. 4B, 5E). It is notable that these latter
Human RGS2 mutations alter vascular reactivity

two mutations reduce RGS2 function by perturbing membrane localization while the other two have different mechanisms (Phan et al., 2017).

Ser46 and Ser64 phosphomimetic mutants of D40Y and R44H RGS2 can rescue protein plasma membrane localization and function

In VSMCs, RGS2 has been shown to be an effector of the NO-cGMP pathway. RGS2 is phosphorylated by PKG1α which is activated by cGMP and as a consequence, RGS2 membrane localization and GAP function is enhanced (Osei-Owusu et al., 2007; Sun et al., 2005a). RGS2 phosphorylation at Ser46 and Ser64 by PKG1α increased plasma membrane (PM) localization and GAP activity of RGS2 protein (Osei-Owusu et al., 2007; Tang et al., 2003b). Given that the two RGS2 mutants mentioned above (D40Y, R44H) had impaired PM localization in HEK293 cells but supported a normal ACh-evoked relaxation response in the MAs, we hypothesized that phosphorylation of D40Y and R44H mutant proteins in VSMCs by the NO-cGMP-PKG pathway activation upon ACh stimulation is able to rescue the impaired membrane localization and function of these mutants. The effects of site-specific phosphorylation on protein activity can be mimicked by mutation of Ser (S) or Thr (T) to Asp (D). Therefore, in order to model the effects of phosphorylation of Ser46 and Ser64 on RGS2 protein localization, we performed mutagenesis to make S46D and S64D mutations of tagged constructs encoding WT, D40Y and R44H (RGS2 WT DD, D40Y DD, R44H DD). The expression levels of the phosphomimetic mutants were similar to their non-phosphorylated proteins and similar to WT RGS2 (Fig. S2). When co-expressed with Gaq Q209L, D40Y and R44H mutant RGS2 remained in the nucleus while RGS2 WT and the phosphomimetic mutants (RGS2 DD, D40Y DD, R44H DD) localized to the PM (Fig. 5A, B). Additionally, the RGS2 D40Y and R44H mutants supported less Ca^{2+} inhibition compared to
Human RGS2 mutations alter vascular reactivity

RGS2 WT (Fig. 5C) while RGS2 D40Y DD and R44H DD suppressed AT1R-mediated Ca\(^{2+}\) mobilization equivalently to RGS2 DD (Fig. 5D).

Effect of PKG inhibition on ACh-mediated relaxation in MAs expressing the D40Y RGS2 mutant

If phosphorylation helps maintain the function of the D40Y mutant RGS2 then inhibition of PKG with Rp-8-pCPT-cGMPS (30 µM) should prevent the rescue of relaxation responses of MAs. PKG inhibition slightly reduced maximal relaxation of MAs expressing WT RGS2 from 99.6 ± 5.5% to 87.8 ± 4.2% (n.s) and shifted the ACh-concentration response curve a half-log to the right (logEC\(_{50}\) -5.8 ± 0.06 vs -6.3 ± 0.09, n.s., Fig. 5E, F, Table 1). The relaxation response of RGS2\(^{-/-}\) MAs transfected with empty vector was impaired (max relaxation 52.9 ± 14.3%), and was further depressed by PKG inhibition (max relaxation 38.4 ± 3.5%, n.s, Fig. 5E, F, Table 1). However, PKG inhibition drastically reduced the dilation of MAs transfected with the D40Y mutant RGS2 (40.3 ± 6.7% vs 98.4 ± 12.3%, p < 0.001, Fig. 5E, F, Table 1). The marked reduction of relaxation response in MAs expressing the D40Y mutant is consistent with a model in which lack of phosphorylation and plasma membrane localization occurs when PKG1\(\alpha\) is inhibited. We did not test MAs expressing R44H mutant in this experimental setting, but given the similarity in mechanisms of the D40Y and R44H at the molecular level, we think the MAs expressing R44H might behave similarly to the MAs expressing D40Y.

Discussion

In this study, we examined the physiological effects of human RGS2 LOF mutations in a resistance artery. Four mutant RGS2 proteins (Q2L, D40Y, R44H, R188H) were previously identified as LOF mutations using a Ca\(^{2+}\) mobilization phenotypic assay in CHO cells (Phan et al.,
Human RGS2 mutations alter vascular reactivity

2017). Here, we report that all four mutant proteins failed to effectively suppress AngII-mediated vasoconstriction in mouse MAs. Interestingly, only the Q2L and R188H mutations exhibited impaired ACh-mediated relaxation. The D40Y and R44H RGS2 mutants supported a normal relaxation response to ACh. We also provide mechanistic evidence that the differential relaxation supported by mutant RGS2 proteins may be attributed to phosphorylation of RGS2 by PKG in VSMCs. It appears that PKG-dependent phosphorylation can rescue PM localization in HEK293 cells and restore the vasorelaxation function of the D40Y and probably the R44H mutant RGS2 in MAs.

Freshly isolated mesenteric artery responses to AngII and ACh

We were able to confirm the previously published effects of acetylcholine in WT and RGS2-deficient MAs (Osei-Owusu et al., 2012). Additionally, we show for the first time that MAs from RGS2−/− mice exhibit augmented vasoconstriction to AngII. This is consistent with previous literature showing that RGS2-deficient renal interlobar arterioles had an increased contraction in response to AngII (Hercule et al., 2007).

Acetylcholine-induced relaxation of mesenteric arteries expressing RGS2 mutant proteins

One component of RGS2-mediated relaxation of VSMC involves PKG-mediated phosphorylation and membrane translocation of RGS2 to inhibit contraction evoked by Gq/11-coupled vasoconstrictor receptors (Sun et al., 2005a; Tang et al., 2003b). RGS2 also promotes endothelium-derived hyperpolarizing factor (EDHF)-dependent vasodilation by blunting Gi/o-dependent processes (Osei-Owusu et al., 2012). In our experiments, the RGS2-GFP proteins were expressed in the VSMC layer but do not appear to be expressed at significant levels in the endothelial cells (Fig. 2B). Therefore, we aren’t able to assess the EDHF-dependent relaxation effect of RGS2 (Osei-Owusu et al., 2012) with our method. However, overexpression of RGS2 in
VSMC appears to be important in mediating ACh-evoked relaxation since over-expression of the WT RGS2 in VSMCs was able to rescue the impaired ACh-mediated relaxation in RGS2<sup>−/−</sup> arteries. Also mutants with different loss of function mechanisms (Phan et al., 2017) behaved differently (Fig. 4).

Acetylcholine mediates relaxation in part by activating the NO-cGMP-PKG pathway in endothelium-intact arteries (Christopoulos and El-Fakahany, 1999; Sun et al., 2005a). RGS2, as an effector of PKG, has previously been shown to be phosphorylated at Ser46 and Ser64 (Tang et al., 2003b), enhancing PM localization. These phosphosites, interestingly, are located close to the sites of the D40Y and R44H mutations in RGS2, as shown in a model of the RGS2 N-terminal helix (Fig. 6) interacting with lipids (Tikhonova et al., 2006). This helix facilitates PM targeting (Gu et al., 2007; Heximer et al., 2001). Introducing phosphomimetic mutants at two PKG1α phosphorylation sites of RGS2 (D40Y DD, R44H DD) in the D40Y and R44H mutant RGS2 proteins enhanced PM localization and function in suppressing Ca<sup>2+</sup> release (Fig. 5 A, B, D). Conversely, PKG inhibition substantially reduced ACh-induced relaxation in RGS2 D40Y expressing RGS2<sup>−/−</sup> MAs (Fig. 5F). These results support our hypothesis that the normal ACh-mediated relaxation response of the D40Y and R44H mutant RGS2 in MAs is due to phosphorylation of mutant proteins by PKG. At the molecular level, this phosphorylation may rescue PM localization of the mutant proteins. The RGS2 Q2L and R188H mutants may not be rescued by phosphorylation since the mechanism of their LOF behavior is not related to PM localization.

Although the RGS2 D40Y and R44H mutant alleles supported a normal relaxation response in resistance arteries, an intact endothelial NO-cGMP pathway was required for this response. When endothelial function is compromised such as in hypertension (Brandes, 2014) or
Human RGS2 mutations alter vascular reactivity

in conditions wherein PKG function is deficient (Michael et al., 2008), RGS2 proteins expressed from these mutant alleles will likely be unphosphorylated, triggering aberrant Gαq signaling and an impaired relaxation response.

How does phosphorylation of RGS2 at Ser46 and Ser64 rescue D40Y and R44H membrane localization?

The RGS2-lipid bilayer interaction was impaired in the R44H mutant according to the snorkeling-dependent stabilization model (Gu et al., 2008a). In the case of the D40Y mutant, the change from a negatively charged Asp residue to a hydrophobic Tyr residue may disrupt the local environment for the anchorage of the adjacent Trp41 to the PM (Gu et al., 2008a). Several mechanisms have been proposed to explain how phosphorylation at these sites might enhance recruitment of RGS2 to the plasma membrane. Salt bridge formation between the phosphorylated Ser residues and adjacent Lys residues (Osei-Owusu et al., 2007) may stabilize the N-terminal amphipathic helix. This could explain how introduction of the Asp phosphomimetic in place of Ser at position 46 and 64 could stabilize the amphipathic α helix disrupted by the D40Y and R44H mutations to rescue function.

RGS2 plays three roles in the vasculature 1) a direct function as a GAP to negate vasoconstrictor actions through Gαq, 2) acting as an effector of NO-cGMP-PKG signaling to promote vasodilation by modulating Gαq-mediated vasoconstrictor action, and 3) promoting EDHF-mediated vasorelaxation (Osei-Owusu et al., 2012). By over-expressing RGS2 in the MAs, we were able to probe the first two functions of these RGS2 mutants in regulating vascular reactivity of MAs. A limitation of this study is the lack of knock-in animal models to allow investigation of whether endogenous RGS2 LOF mutants affect whole body blood pressure responses. Also, we are unable to assess their effects on the central nervous system or the kidney.
Human RGS2 mutations alter vascular reactivity

Nevertheless, our data provide a new understanding how human RGS2 mutants behave in VSMCs in the resistance vasculature. We also provide molecular evidence for functional differences among mutant alleles where the function of D40Y or R44H mutants can be rescued by PKG-mediated phosphorylation. These results provide critical insights for precision therapeutic approaches to individuals bearing particular RGS2 mutations and may facilitate drug discovery to target these rare individuals.

Human RGS2 mutations alter vascular reactivity

Figure legends

Fig 1. Vascular reactivity of RGS2^{+/+} and ^{-/-} arteries to vasoconstrictor phenylephrine (PE) and angiotensin II (AngII) and vasodilator acetylcholine (ACh). A. Mesenteric arteries from RGS2^{+/+} and RGS2^{-/-} mice responded similarly to different concentrations of PE. B. Aorta isolated from RGS2^{-/-} mice showed greater sensitivity to PE than aorta from RGS2^{+/+} mice. C. Mesenteric arteries response to AngII (5nM). D. Concentration response of ACh-induced vasodilation expressed as percentages of increase in arterial diameter after constriction with PE (3x10^{-6} M) (n=5). The data are expressed as the mean ± S.E; *, **, ***, ****, p < 0.05, 0.01, 0.001, 0.0001, respectively, versus WT (two-way ANOVA) with Sidak post-test; n value indicates the number of mice used to isolated vessels for each experiments.

Fig 2. Reversible permeabilization permits transfection of RGS2-GFP into RGS2^{-/-} mesenteric arteries. 2-3 days post reversible permeabilization (described in “Materials and methods”), arteries were stained for rabbit GFP, and labelled with Cy3-anti rabbit secondary antibody. The arteries were mounted to slide using ProLong™ Gold Antifade Mountant and visualized using confocal microscopy. A. Expression of RGS2-GFP is detected compared with arteries exposed to empty vector. B. RGS2-GFP was overexpressed in vascular smooth muscle cells but not endothelial cells (arrow heads). C. Representative images showed whole vessel expression of RGS2-GFP. Expression level of the Q2L mutant in the MAs is lower than that of RGS2-WT and other mutant RGS2 proteins. The round circle below the cell in the middle DAPI image is an artifact that appears to be a bubble.

Fig 3. Loss of function mutations of RGS2 failed to suppress AngII-mediated vasoconstriction. RGS2-GFP constructs were introduced to mesenteric arteries isolated from RGS2^{-/-} mice by reversible permeabilization. RGS2 WT, M5V and A99G (2 normal function
mutations (Phan et al., 2017)) expressing arteries reduced vascular contraction upon 50nM AngII stimulation while the other mutants did not. D40Y, R44H and R188H mutant expressing arteries showed a significantly elevated contractile response to 50nM AngII stimulation compared to RGS2 WT expressing arteries. * p < 0.05 compared to empty vector, # p < 0.05 compared to WT, one-way ANOVA with Dunnett post-test.

**Figure 4. Differential effects of RGS2 missense mutations on acetylcholine-mediated vasorelaxation.** A. RGS2-GFP expression in RGS2−/− mesenteric arteries rescued ACh-mediated relaxation. RGS2 WT expressing arteries showed enhanced relaxation compared to empty vector transfected arteries. Q2L and R188H expressing arteries showed less relaxation compared to RGS2 WT expressing arteries. B. D40Y and R44H expressing arteries, however, showed comparable relaxation response to RGS2 WT. The data are expressed as the mean ± S.E; *, ***, ****, p < 0.05, 0.001, 0.0001, respectively, versus WT (two-way ANOVA) with Dunnett post-test.

**Figure 5. Effects of phosphorylation on RGS2 localization and function.** A. Representative confocal images showing that phosphomimetic mutations of D40Y and R44H rescued the mutants’ membrane localization and function in HEK293 cells. When co-expressed with Gaq Q209L, D40Y, R44H remained in the nucleus while RGS2 WT, RGS2 DD, D40Y DD, R44H DD localized to the plasma membrane. B. Quantification of protein localization of at least 80 live cells from 3 – 4 independent experiments; *, **** p < 0.05, 0.0001, respectively, using one-way ANOVA with Bonferroni post-test. C. LOF phenotype of the D40Y and R44H mutant RGS2 in Ca^{2+} assay in CHO cells. D. D40Y DD and R44H DD suppressed AT1R-mediated Ca^{2+} mobilization as well as RGS2 DD. E. The D40Y mutant RGS2 supported a normal ACh-mediated relaxation response. F. PKG inhibition by 30 µM Rp-8-pCPT-cGMPS significantly reduced vascular relaxation in D40Y expressing MAs, n value indicates the number of mice used to isolated vessels for each

experiments. The data are expressed as the mean ± S.E; *, ***, ****, p < 0.05, 0.001, 0.0001, respectively, using two-way ANOVA with Dunnett post-test.

**Figure 6. Modelled structure of full-length RGS2 with lipid membrane.** N-terminal amphipathic α-helix is orientated parallel with membrane, allowing interactions between amino acid side chains and components of lipid(Tikhonova et al., 2006). Mutated sites (D40, R44) are labeled in blue. Phosphorylated sites (S46, S64) are marked as spheres. The phosphate groups of lipid are in orange; the lipid acyl chains are in cyan.
