AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; AMPAR, AMPA receptor; CP-AMPARs, calcium permeable AMPARs; glu, glutamate; $I_{\text{peak}}$, peak current; $I_{\text{ss}}$, steady-state current; JNJ-118, JNJ-55511118; LBD, ligand binding domain; NSFA, non-stationary fluctuation analysis; $P_o, \text{peak}$, peak open probability; RI, rectification index; TARP, transmembrane AMPAR regulatory protein; TM, transmembrane.
Abstract

AMPARs mediate excitatory signaling in the brain and are therapeutic targets for the treatment of diverse neurological disorders. The receptors interact with a variety of auxiliary subunits, including the transmembrane AMPAR regulatory proteins (TARPs). The TARPs influence AMPAR biosynthesis and trafficking and enhance receptor responses by slowing desensitization and deactivation and increasing single-channel conductance. TARP γ8 has an expression pattern that is distinct from other TARPs, being enriched in the hippocampus. Recently, several compounds have been identified that selectivity inhibit γ8-containing AMPARs. One such inhibitor, JNJ-55511118, has shown considerable promise for the treatment of epilepsy. However, key details of its mechanism of action are still lacking. Here, using patch-clamp electrophysiological recording from heterologously expressed AMPARs, we show that JNJ-55511118 inhibits peak currents of γ8-containing AMPARs by decreasing their single-channel conductance. The drug also modifies hallmark features of AMPAR pharmacology, including the TARP-dependent actions of intracellular polyamines and the partial agonist kainate. Moreover, we find that JNJ-55511118 reduces the influence of γ8 on all biophysical measures, aside from its effect on the recovery from desensitization. The drug is also effective when applied intracellularly, suggesting it may access its binding site from within the membrane. Additionally, we find that AMPARs incorporating TARP γ2 mutated to contain the JNJ-55511118 binding site, exhibit greater block than seen with AMPARs containing γ8, potentially reflecting differences in TARP stoichiometry. Taken together, our data provide new insight into the mechanism by which γ8-selective drugs inhibit AMPARs.
Significance statement

While modulation of AMPA-type glutamate receptors shows promise for the treatment various neurological conditions, the absence of subtype-selective drugs has hindered adoption of this therapeutic strategy. We made patch-clamp recordings to characterize the actions of the γ8-selective AMPAR inhibitor JNJ-5551118 on GluA2(Q) receptors expressed in HEK cells. We report that JNJ-5551118 inhibits AMPAR-mediated currents by reducing single-channel conductance, providing clear insight into the mechanism of action of this important class of AMPAR modulators.
Introduction

AMPA-type glutamate receptors are responsible for fast signaling and the expression of plasticity at excitatory synapses throughout the CNS (Hansen et al., 2021). Manipulation of AMPAR activity has been actively pursued as a possible therapy for various neurological and psychiatric disorders, including stroke, depression, pain, epilepsy, and cognitive deficit in Alzheimer’s disease (Brogi et al., 2019; Lynch, 2006; Rogawski, 2011). Although a plethora of AMPAR positive- and negative allosteric modulators (PAMs and NAMs) have been developed (Frydenvang et al., 2021; Partin, 2015; Stenum-Berg et al., 2019) these lack selectivity for different brain regions. This is because, while AMPARs formed from various combinations of the four core subunits (GluA1-4) show differential distribution, the subunits are structurally highly homologous. For example, the NAM perampanel has proved effective against multiple seizure types (Hanada, 2020; Potschka and Trinka, 2019; Tsai et al., 2018), but its lack of regional specificity is thought to contribute to side effects that include ataxia and dizziness (Villanueva et al., 2021; Zwart et al., 2014).

The biophysical and pharmacological properties of AMPARs depend not only on their subunit composition but also on their complement of associated proteins or auxiliary subunits (Coombs and Cull-Candy, 2021; Ishii et al., 2020; Jackson and Nicoll, 2011; Matthews et al., 2021). Of the several families of recognized AMPAR auxiliary subunits, the transmembrane AMPAR regulatory proteins (TARPs; γ2, -3, -4, -5, -7 and -8) have been the most extensively studied. Crucially, the various TARP family members are distributed differentially throughout the brain (Fukaya et al., 2005), potentially offering pharmacological targets with regional specificity (Zwart et al., 2014). Recently a novel group of compounds were developed that selectively inhibit...
AMPAR complexes containing TARP γ8 (Gardinier et al., 2016; Kato et al., 2016; Maher et al., 2016; Ravula et al., 2018; Savall et al., 2019). Such AMPARs are enriched in neurons of the forebrain, including in hippocampal CA1 cells (Fukaya et al., 2005; Rouach et al., 2005). In preclinical studies the γ8-selective blockers JNJ-55511118 (‘JNJ-118’) and LY3130481 have shown considerable promise as treatments for epilepsy, with efficacy similar to that of perampanel but without the undesirable motor side effects (Kato et al., 2016; Maher et al., 2016).

JNJ-118 shows >1000-fold selectivity for γ8-containing AMPARs (Maher et al., 2016). The drug partially inhibits both peak- and steady state glutamate-evoked currents, while accelerating the kinetics of deactivation and desensitization (Dohrke et al., 2020; Maher et al., 2016). Mutagenesis, molecular modelling and cryo-EM studies have shown that the JNJ-118 binding site lies between the third and fourth transmembrane regions (TM3 and TM4) of γ8 and the first membrane region (M1) of adjacent AMPAR subunit (Dohrke et al., 2020; Lee et al., 2017; Maher et al., 2016; Yu et al., 2021). Selectivity of the drug for AMPARs containing γ8, over those containing other TARP family members, depends on the presence of two amino acid residues within TM3 and TM4 of γ8. Replacing these residues abolishes JNJ-118 sensitivity, while introducing them into TARP γ2 renders AMPARs containing this mutated TARP sensitive to JNJ-118 (Maher et al., 2016).

Despite the identification of a binding pocket for JNJ-118, it remains unclear exactly how the drug diminishes the AMPAR response. Thus, while JNJ-118 inhibits the peak and steady state glutamate-evoked current of γ8-associated AMPARs (Maher et al., 2016), it is not known whether this reflects a reduction in the number of
functional receptors, a reduction in single-channel conductance, or a change in channel gating. Here we examine the action of JNJ-118 on homomeric GluA2(Q) AMPARs containing γ8 or doubly mutated γ2. We show that, in addition to decreasing peak- and fractional steady-state currents and the time constants of deactivation and desensitization, JNJ-118 decreased the weighted mean single-channel conductance by reducing the proportion of high conductance openings. JNJ-118 also increased channel block by intracellular spermine and decreased the efficacy of the partial agonist kainate but did not affect recovery from desensitization. Thus, for all but one parameter examined, JNJ-118 appears to reduce the influence of TARP on AMPAR function.

Materials and Methods

Heterologous expression. We expressed recombinant AMPAR subunits and TARPs (plus EGFP) in HEK293T/17 cells (mycoplasma-free) from ATCC. These were maintained under standard protocols, as described previously (Coombs et al., 2017). Rat GluA2 flip cDNA was unedited at the Q/R site (Q-form) and R/G edited. γ2 and γ8 cDNA were from rat. cDNA for γ8.dm, carrying mutations G210A and V177I that completely abolish activity of JNJ-118 (Maher et al., 2016), was from human and was a gift from Michael Maher (Janssen Research & Development L.L.C., San Diego, CA, USA). Double point mutations in γ2 (A184G and I153V; γ2.dm), corresponding to those shown to confer sensitivity to inhibition by JNJ-118 to human γ2 (Maher et al., 2016), were produced using standard PCR. AMPAR/TARP combinations were transfected at a cDNA ratio of 1:2. Transient transfection was performed using Lipofectamine 2000 (Life Technologies). Cells were split 12–30 h
after transfection and plated on glass coverslips treated with poly-L-lysine.

Electrophysiological recordings were performed 18–48 h later.

**Electrophysiology.** Cells were viewed using a fixed-stage microscope (Axioskop FS1, Zeiss) and perfused at a rate of 1.5–2 ml min\(^{-1}\) with an external solution containing 145 mM NaCl, 2.5 mM KCl, 1 mM CaCl\(_2\), 1 mM MgCl\(_2\), and 10 mM HEPES, pH 7.3. Patch-clamp electrodes were pulled from borosilicate glass (1.5 mm o.d., 0.86 mm i.d.; Harvard Apparatus) and fire polished to a final resistance of 8–12 MΩ. The internal solution contained 145 mM CsCl, 2.5 mM NaCl, 1 mM Cs-EGTA, 4 mM MgATP, and 10 mM HEPES (pH 7.3 with CsOH) supplemented with 100 μM spermine tetrahydrochloride (Tocris Bioscience). Recordings were made from outside-out patches at 22–25 °C using an Axopatch 200B amplifier (Molecular Devices). Currents were recorded at −60 mV, low-pass filtered at 10 kHz, and digitized at 20 kHz using an NI USB-6341 (National Instruments) interface with Strathclyde Electrophysiology Software WINWCP (John Dempster, University of Strathclyde, Glasgow UK).

**Rapid agonist application to excised patches.** Rapid agonist application was achieved by switching between continuously flowing solutions. Solution exchange was achieved by moving an application tool made from theta glass (Hilgenberg) or triple barreled glass (Vitrocom) mounted on a piezoelectric translator (Physik Instrumente). JNJ-5551118 (Tocris) was used at the indicated concentrations. The 10–90% exchange time, assessed by jumping open electrodes into a diluted solution and observing junction potential changes, were between 120–300 μs.
Data analysis. Records were analyzed using Igor Pro 6.35 (Wavemetrics) with Neuromatic 2.8 (http://www.neuromatic.thinkrandom.com/). Entry into desensitization (200 ms application of 10 mM glutamate) and current deactivation (1-2 ms application of 10 mM glutamate) were fitted with the sum of two exponentials and the weighted time constants ($\tau_{w,\text{des}}$ and $\tau_{w,\text{deact}}$) calculated, according to:

$$\tau_w = \tau_f \left( \frac{A_f}{A_f + A_s} \right) + \tau_s \left( \frac{A_s}{A_f + A_s} \right)$$

where $A_f$ and $\tau_f$ are the amplitude and time constant of the fast component and $A_s$ and $\tau_s$ are the amplitude and time constant of the slow component.

Non-stationary fluctuation analysis was performed on the decaying phase of currents evoked by 1 or 200 ms applications of 10 mM glutamate (30–200 successive applications), as previously described (Soto et al., 2007). The variance for each successive pair of current responses was calculated and the single-channel current ($i$) and total number of channels ($N$) were then determined by plotting the ensemble variance ($\sigma^2$) against mean current ($\bar{i}$) and fitting with a parabolic function:

$$\sigma^2 = i\bar{i} - \bar{i}^2/N + \sigma_B^2$$

where $\sigma_B^2$ is the background variance. The weighted mean single-channel conductance was calculated from the single-channel current and the holding potential.

Records used for single-channel analysis were digitally filtered at 4 kHz and individual channel events were selected by eye. Channel openings were analyzed using QuB (ver. 2.0.0.20; https://qub.mandelics.com). The amplitude of the resolved openings was measured from either the entire opening when they occurred during steady-state, or from closing transitions alone (final current level to adjacent baseline) when part of the initial decay. Ambiguous events were excluded from
analysis. Measured openings (at −60 mV) were binned by current and fitted using a multi-peak Gaussian function (IGOR Pro).

Rectification index, RI ($I_{+60}/I_{-60}$), was calculated as the ratio of peak currents at +60 mV/−60 mV. G-V relationships were calculated from peak currents measured at 10 mV intervals between −110 and +80 mV. TARP-free GluA2 currents displayed minimal outward rectification and G-V curves were fitted with the Boltzmann equation:

$$G = G_{\text{max}} \left( \frac{1}{1 + \exp \left( \frac{V_m - V_b}{k_b} \right)} \right)$$

where $G_{\text{max}}$ is the conductance at a sufficiently hyperpolarized potential to produce full relief of polyamine block, $V_m$ is the membrane potential, $V_b$ is the potential at which 50% of block occurs, and $k_b$ is a slope factor describing the voltage dependence of block (the membrane potential shift necessary to cause an e-fold change in conductance). GluA2 co-expressed with TARPs displayed double rectification necessitating G-V curves be fitted with a double Boltzmann equation containing equivalent terms for voltage-dependent permeation (p) (Panchenko et al., 1999):

$$G = G_{\text{max}} \left( \frac{1}{1 + \exp \left( \frac{V_m - V_b}{k_b} \right)} \right) + G_{\text{max,p}} \left( \frac{1}{1 + \exp \left( \frac{V_m - V_p}{k_p} \right)} \right)$$

$V_b$ values from both Boltzmann equations were compared between conditions. Recovery from steady-state desensitization was measured following a 300 ms equilibrating application of 10 mM glutamate. The recovery of glutamate activated peak currents was measured following 2–500 ms intervals in control solution and fit
with a single exponential to obtain the time constant of recovery ($\tau_{\text{rec}}$). The kainate:glutamate ratio ($I_{KA}/I_{Glu}$) was measured by dividing the current produced by 50 μM kainate by that produced by 1 mM glutamate in the continuous presence of 50 μM cyclothiazide.

**Data presentation and statistical analysis.** Summary data are presented in the text and in **Table 1**, **Table 2** and **Table 3** as mean ± standard deviation (s.d.) from n patches together with paired or unpaired mean differences with 95% confidence intervals [lower bound, upper bound] and p-values from one- or two-sample tests. Statistical tests were performed using R (version 4.1.1, the R Foundation for Statistical Computing, https://www.r-project.org/) and R Studio (version 1.4.1717, RStudio). Bias corrected and accelerated (BCa) confidence intervals were calculated from 5000 bootstrap resamples using the dabestr package (Ho et al., 2019). Normality was not tested statistically but gauged from density histograms and/or quantile-quantile plots. On the basis of this, non-parametric tests were used throughout. Although illustrated separately in the figures, for each measure a statistical comparison was performed across the five different receptor types (GluA2, GluA2/γ8, GluA2/γ8.DM, GluA2/γ2 and GluA2/γ2.DM) as a single combined analysis. In the case of $I_{KA}/I_{Glu}$, only GluA2, GluA2/γ8 and GluA2/γ2.DM were examined, thus the statistical comparison was performed across three different receptor types. Omnibus tests were performed using Kruskal-Wallis rank sum test or rank-based longitudinal (repeated measures) analysis using the nparLD package (Noguchi et al., 2012). One- or two-sample tests were performed using one-sample Wilcoxon signed rank tests (against 100%), Wilcoxon signed rank tests for paired comparisons, or Wilcoxon rank sum tests for unpaired comparisons. For pairwise tests, calculated p-
values were adjusted for multiple comparisons within each separate family of comparisons using Holm’s sequential Bonferroni correction (mt.rawp2adjp function in the R package multtest; Pollard et al., 2005). The results of the different families of statistical tests (one for each measure) are presented in Tables 1-3 and Table S1. No statistical test was used to predetermine sample sizes; these were based on standards of the field. No randomization was used.

**Results**

**JNJ-118 decreases peak current and modifies kinetics of GluA2(Q)/γ8**

We initially examined the actions of JNJ-118 on responses evoked by fast application of glutamate (10 mM, 200 ms, −60 mV) onto outside-out patches from HEK293T/17 cells expressing GluA2(Q) in the absence or presence of TARP γ8. As expected, 1 μM JNJ-118 had no effect on glutamate-evoked peak currents in the absence of γ8 but substantially reduced these (by ~40%) in the presence of γ8 (Fig 1a,b and Table 1). In cells transfected with GluA2 and a mutated γ8 (γ8.dm) lacking the two amino acid residues previously shown to be critical in forming the JNJ-118 binding site (Maher et al., 2016; γ8.dm), the effect of JNJ-118 was lost (Fig 1a,b and Table 1).

Both γ8 and γ8.dm increased the weighted mean time constant of desensitization ($\tau_{w,\text{des}}$) and the fractional steady-state component ($I_{ss}/I_{peak}$) seen with 200 ms glutamate applications, as well as the weighted mean time constant of deactivation ($\tau_{w,\text{deact}}$) following 1-2 ms glutamate applications (Table 2). These observations confirm the incorporation of the TARPs into functional AMPARs (Cho et al., 2007). In accord with the TARP-dependent effects on peak amplitude, 1 μM JNJ-118
decreased $\tau_{w, \text{des}}$, $I_{\text{ss}}/I_{\text{peak}}$ and $\tau_{w, \text{deact}}$ of GluA2/γ8 but had no effect on these measures from GluA2/γ8,DM (Table 2, Table S1, Fig S1).

Overall, the effects of JNJ-118 on peak current, fractional steady-state current, deactivation and desensitization of GluA2/γ8 were qualitatively comparable to those originally observed with GluA1/γ8 receptors (Maher et al., 2016). Of note, while the effects of JNJ-118 we observed were marked, in the presence of the drug the values of $\tau_{w, \text{deact}}$, $\tau_{w, \text{des}}$ and $I_{\text{ss}}/I_{\text{peak}}$ remained different from those seen with GluA2 alone (Table 2; $\tau_{w, \text{deact}}$ unpaired mean difference GluA2/γ8/JNJ-118 minus GluA2/JNJ-118 0.48 ms [0.23, 0.86], $p = 0.026$; $\tau_{w, \text{des}}$ 2.79 ms [1.84, 4.01], $p < 0.0001$; $I_{\text{ss}}/I_{\text{peak}}$ 1.84 % [1.03, 2.76], $p = 0.0095$), suggesting that the drug does not simply eliminate these functional effects of γ8.

The proportion of higher-conductance channel openings is reduced by JNJ-118

Although the effect of JNJ-118 on desensitization is consistent with its effect on the steady-state current, it cannot easily account for the decrease in peak current. Indeed, an inhibitory effect of JNJ-118 on peak response persists when desensitization is blocked by cyclothiazide (Maher et al., 2016). However, as TARPs are known to increase AMPAR channel conductance – either by increasing the prevalence of high conductance openings or by increasing the absolute conductance (Shelley et al., 2012; Tomita et al., 2005) – a reduction in this effect could account for the inhibition of peak current (Maher et al., 2016). To investigate this, we used non-stationary fluctuation analysis (NSFA), an approach we have previously shown to capture the increased weighted mean channel conductance caused by TARP-association (Coombs et al., 2012; Soto et al., 2007; Soto et al., 2009). NSFA (Fig 2a) revealed that co-assembly with wild-type or mutated γ8 increased the weighted mean
single-channel conductance and peak open probability ($P_{o, \text{peak}}$) of GluA2 (Fig 2b and Table 3). As seen with peak current, $\tau_w, \text{des}$ and $I_{ss}/I_{peak}$, JNJ-118 (1 μM) decreased both the weighted mean conductance and $P_{o, \text{peak}}$ of GluA2/γ8 but not of GluA2/γ8.DM (Fig 2b and Table 3).

To establish whether the reduction in mean channel conductance produced by JNJ-118 arose from a uniform or differential effect on sub-conductance levels, we next examined individual channel openings from outside-out membrane patches that contained only a small number of receptors. Glutamate (10 mM) was applied for 200 ms (Fig 3a) and channel amplitudes measured from well-resolved openings (see Methods). Both in the absence and presence of JNJ-118 the histogram of channel amplitudes (pooled from 6 and 7 patches, respectively) could be fitted with three Gaussian components, identifying three main conductance states of approximately 23, 32 and 43 pS (Fig 3b). While the absolute positions of these peaks were unaffected by JNJ-118, the relative prevalence of the lowest conductance was increased (from 28% to 63%) (Fig 3b). These data suggest that the effect of JNJ-118 can be ascribed to a reduction in the proportion of the higher conductance openings, rather than a decrease in the mean amplitude of all sublevels.

**JNJ-118 reduces the effect of γ8 on GluA2(Q) spermine block**

TARP co-assembly with AMPARs has previously been shown to attenuate channel block of GluA2(R)-lacking calcium permeable (CP-) AMPARs by endogenous intracellular polyamines (Brown et al., 2018; Cho et al., 2007; Coombs et al., 2021; Soto et al., 2007; Soto et al., 2009). As our data on channel conductance and kinetics indicate that the effects of JNJ-118 correspond to a partial masking of the
influence of γ8, and polyamine block is influenced by ion flux (Bowie et al., 1998), we
next asked whether TARP attenuation of polyamine block was similarly affected by
the drug. Thus, we examined the effect of JNJ-118 on the voltage-dependence of
GluA2, GluA2/γ8 and GluA2/γ8.DM current amplitude in the presence of intracellular
spermine (100 µM) (Fig 4a). The rectification index (RI; \(I_{+60}/I_{-60}\)) was increased when
GluA2 was co-expressed with either γ8 or γ8.DM (Fig 4b), consistent with the view
TARP incorporation decreases spermine block. Application of 1 µM JNJ-118,
decreased the RI for GluA2/γ8 but not that for GluA2 expressed alone or co-
expressed with γ8.DM (Table 3).

To probe further the effect of JNJ-118 on spermine block we generated conductance-
voltage (\(G/V\)) relationships for the different receptor/TARP combinations (Fig 4c).
This revealed a drug-induced depolarizing shift in \(V_b\) (voltage giving 50% block in the
negative limb of the double Boltzmann fit) for GluA2/γ8, but not for GluA2 alone nor
for GluA2/γ8.DM (Table 3). This is consistent with the view that spermine block (on
GluA2/γ8) is increased in the presence of JNJ-118. However, it is of note that in the
presence JNJ-118 the \(V_b\) value for GluA2/γ8 did not return to its TARP-free value
(Fig 4c, Table 3; \(V_b\) unpaired mean difference GluA2/γ8/JNJ-118 minus GluA2/JNJ-
118 24.1 mV [18.7, 31.9] \(p = 0.0087\)).

Lack of effect of channel-gating state on JNJ-118 inhibition

It has been suggested that binding of γ8-selective NAMs to TM3 and TM4 of γ-8 may
hamper AMPAR channel opening by interfering with M3 motion, restricting expansion
of the M3 gating helices (Lee et al., 2017; Yu et al., 2021). If this is indeed the case,
it seems possible that the JNJ-118 binding site could be occluded by agonist-induced
movement of the M3 domain. Thus, we next sought to determine whether the drug produced similar inhibition when applied to receptors with open or closed channels. We first examined JNJ-118 inhibition by applying 1 μM JNJ-118 for 200 ms immediately prior to the fast application of glutamate in the absence of JNJ-118 (Fig 5a, see Methods). A single application of JNJ-118 to receptors with closed channels was sufficient to cause 23 ± 15.9% (mean ± s.d., n = 7) inhibition of the subsequent glutamate response. Following several applications, the extent of inhibition stabilized at ~30% (Fig 5a).

We next asked whether JNJ-118 was effective against receptors with open channels. These experiments were performed in the presence of the PAM cyclothiazide (50 μM) to suppress AMPAR desensitization. We were mindful that AMPARs containing γ8 can slowly transition into high conductance and high open probability states following activation. This process, termed superactivation (Carbone and Plested, 2016) or resensitization (Kato et al., 2010), is seen as a slow ‘run-up’ in current, and is particularly evident in the presence of cyclothiazide (Carbone and Plested, 2016; Riva et al., 2017). To allow for the development of superactivation we used an 8 s pre-conditioning application of glutamate and cyclothiazide before applying JNJ-118. Following activation, as expected, GluA2/γ8 receptors displayed a slow run up (Fig 5b; 23.7 ± 18.8%, n = 7) qualitatively similar to that previously reported (Riva et al., 2017). After a rapid switch to a glutamate/cyclothiazide solution containing 1 μM JNJ-118, currents were inhibited by 39.9 ± 7.7%. The block proceeded with a weighted time constant (τ\text{block}) of 471 ± 225 ms while on removal of JNJ-118, unbinding was slow (τ\text{unblock} 11.8 ± 8.2 s). Given the extremely high open probability expected for superactive GluA2/γ8 receptors in the presence of cyclothiazide (Carrillo et al.,
2019), these receptors would be closed for only a small fraction of the time. Despite this, the onset of block of the open receptors was qualitatively similar to the kinetics of block of closed receptors (Fig 5a). Taken together these observations suggest that the JNJ-118 binding site is not occluded by channel opening.

**JNJ-118 is effective when present in the intracellular medium**

Binding of γ8-selective NAMs occurs within the transmembrane region of the AMPAR complex (Dohrke et al., 2020; Kato et al., 2016; Maher et al., 2016; Yu et al., 2021). Although access from the extracellular milieu has been postulated for LY3130481/CERC-611 (Dohrke et al., 2020; Lee et al., 2017), we wondered whether JNJ-118 could access its binding site from within the lipid bilayer. If this were the case, JNJ-118 might be expected to be effective when included in the intracellular recording solution. To test this, we supplemented the pipette solution with 1 or 10 μM JNJ-118 (JNJ-118\textsubscript{int}), and examined whether glutamate-evoked currents remained sensitive to extracellular applications of the drug (1 μM JNJ-118\textsubscript{ext}) (Fig 5c). We found that the JNJ-118\textsubscript{ext}-sensitive component of glutamate/cyclothiazide currents was reduced by JNJ-118\textsubscript{int}. Specifically, 1 μM JNJ-118\textsubscript{int} reduced the inhibition caused by 1 μM JNJ-118\textsubscript{ext} from ~40% inhibition in control (Fig 5b) to 21.8 ± 16.2% (n = 6), while 10 μM JNJ-118\textsubscript{int} reduced inhibition further, to just 10.9 ± 10.6% (n = 7) (Fig 5d). Thus, JNJ-118 appears able to access its binding site from the lipid bilayer. While it is formally possible that JNJ-118 may bind at an additional 'intracellular' site that occludes, via allostery, its action from the outside, in structural studies such binding has not been observed (Yu et al., 2021).

**Functional effects of incorporating a JNJ-118 binding site into TARP γ2**
Although the action of JNJ-118 is γ8-selective, a JNJ-118 binding site can be incorporated into TARP γ2 by introducing mutations which are the inverse of those that remove the binding site from γ8 (Maher et al., 2016). Thus, receptors containing doubly mutated γ2 (γ2.DM) were previously shown, in a whole cell Ca\(^{2+}\) influx assay, to be sensitive to JNJ-118 (Maher et al. 2016). However, details of the block were not described. To address this, we compared the effects of JNJ-118 on currents produced by fast application of glutamate onto GluA2/γ2 and GluA2/γ2.DM (Fig 6a, Fig S2a).

As expected, JNJ-118 had no effect on the peak current, fractional steady-state current, desensitization or deactivation kinetics of wildtype GluA2/γ2. By contrast, it decreased the peak (Fig 6b) and fractional steady-state currents, while accelerating the desensitization and deactivation kinetics of GluA2/γ2.DM (Table 1, Table 2, Fig S2a). Interestingly, with GluA2/γ2.DM the inhibition of peak amplitude by JNJ-118 was somewhat greater than that seen with GluA2/γ8 (Table 1) (unpaired mean difference GluA2/γ8 minus GluA2/γ2.DM −13.7 % [−19.9, −6.4], p = 0.0021).

Examination of the voltage-dependence of currents in the presence of intracellular spermine (Fig S2b) showed that when GluA2 was co-expressed with either γ2 or γ2.DM, RI was increased and \(V_b\) shifted to more depolarized values (Table 3). While application of 1 μM JNJ-118 affected neither measure for GluA2/γ2, it decreased RI and caused a hyperpolarizing shift in \(V_b\) of GluA2/γ2.DM (Fig S2b, Table 3).

As with γ8-containing receptors, we next examined the effect of JNJ-118 on channel conductance of γ2-containing receptors. NSFA indicated that JNJ-118 decreased the weighted mean single-channel conductance and peak open probability of
GluA2/γ2.DM but not of GluA2/γ2 (Fig 6c; Table 3). Again, in patches containing few channels we resolved the single-channel openings during the steady-state period that followed the initial peak current. Looking jointly at channels resolved in two control and three JNJ-118-treated patches, revealed the presence of three conductance levels (with means of approximately 24, 31, 42 pS). These states contributed 0%, 42% and 58% of openings in control conditions, compared with 49%, 41% and 10% in the presence of JNJ-118 (Fig 6d). Hence, as with γ8-associated receptors, JNJ-118 increased the proportion of lower conductance openings arising from GluA2/γ2.DM.

**JNJ-118 influences agonist efficacy but not recovery from desensitization**

The well-documented increase in AMPAR agonist efficacy induced by TARPs is most readily seen in their effects on the action of the partial agonist kainate, specifically the kainate/glutamate current amplitude ratio ($I_{KA}/I_{Glu}$) (Cho et al., 2007; Tomita et al., 2005). We measured $I_{KA}/I_{Glu}$ for GluA2, GluA2/γ8 and GluA2/γ2.DM in the presence of cyclothiazide (Fig 7a). For GluA2 expressed in the absence of TARP, the relative kainate efficacy was low and, as expected, JNJ-118 had no effect on $I_{KA}/I_{Glu}$ (Table 3). However, $I_{KA}/I_{Glu}$ was increased by γ8 and γ2.DM, and in both cases it was reduced by JNJ-118 (Fig 7b; Table 3). For both GluA2/γ8 and GluA2/γ2.DM the relative kainate efficacy in JNJ-118 remained higher than the value seen for GluA2 alone (unpaired mean difference GluA2/γ8/JNJ-118 minus GluA2/JNJ-118 0.305 [0.202; 0.421] p = 0.0038 and GluA2/γ2.DM/JNJ-118 minus GluA2/JNJ-118 0.368 [0.324; 0.420] p = 0.0038). This finding differs from earlier work, where kainate efficacy was unaffected by JNJ-118 (Maher et al., 2016). One possible explanation for the apparent difference may be the use of cyclothiazide in our experiments, which will
have minimized any influence of desensitization, thus producing a measure which solely reflected relative agonist efficacy.

As the effects of JNJ-118 on the AMPAR properties examined so far appeared consistent with a partial reversal of the modulating influence of TARPs, we also examined the effect of JNJ-118 on the recovery from desensitization of GluA2/γ8 (Fig 7c) and GluA2/γ2.DM receptors. The effects of TARPs on the recovery of AMPARs from desensitization depend on the GluA subunit and TARP isoform. In the case of homomeric GluA2 receptors, we have shown previously that γ2 co-expression has little effect while γ8 markedly slows recovery (Cais et al., 2014). Therefore, as expected, while co-expression of γ8 or γ8.DM slowed recovery from desensitization (by 4-5-fold), neither γ2 nor γ2.DM altered recovery kinetics of GluA2 (Table 1; Fig 7d). Interestingly, JNJ-118 (1 μM) did not affect the recovery kinetics of either GluA2/γ8 or GluA2/γ2.DM (Table 2). Thus, of the various kinetic parameters we examined, only recovery from desensitization appeared insensitive to JNJ-118. This echoes the finding with homomeric GluA1, where the action of γ8 – which is known to speed recovery (Devi et al., 2020) – was also unaffected by JNJ-118 (Maher et al., 2016).

Discussion

γ8-specific AMPAR inhibitors offer an exciting new avenue for the targeted treatment of various neurological and neuropsychiatric disorders as they lack side effects associated with broad spectrum AMPAR antagonists (Gardinier et al., 2016; Kato et al., 2016; Maher et al., 2016; Maher et al., 2017). For heteromeric GluA1/2 γ8-containing receptors the binding site of one of these molecules, JNJ-118, has been
shown to reside between the M1 region of GluA1 and the TM3 and TM4 regions of γ8, suggesting the drug could act by lessening the influence of γ8 on AMPAR function (Dohrke et al., 2020; Lee et al., 2017; Maher et al., 2016; Yu et al., 2021).

Our experiments aimed to build on this information by examining how binding of JNJ-118 changes AMPAR gating and channel behavior.

**Partial activation of AMPAR channels in the presence of JNJ-118**

While the AMPAR/TARP stoichiometry of both recombinantly expressed and native receptors is variable (Dawe et al., 2019; Kim et al., 2010; Shi et al., 2009; Twomey et al., 2016) γ8-containing AMPARs are thought to contain two copies of the TARP, as evidenced from antibody shift assays (Schwenk et al., 2012) and cryo-EM visualization of hippocampal AMPARs (Yu et al., 2021). In native and recombinant heteromeric GluA2- and γ8-containing AMPARs, the GluA2 subunit occupies the gating-dominant ‘pore-distal’ (B/D) positions, and the extracellular loops of γ8 (in the B’/D’ positions associated with GluA2) are thought to directly interact with the GluA2 LBD to modulate receptor gating (Herguedas et al., 2019; Yu et al., 2021). In the native GluA1/GluA2/γ8/CNIH2 receptors visualized by Yu et al. (2021), γ8 forms extensive contacts with both the GluA1 and GluA2 subunits in the TM regions. However, the two JNJ-118 binding sites are formed exclusively from γ8 and the M1 domain of GluA1. Yu et al. (2021) proposed that binding of the drug may decrease receptor activity by precluding movement of the GluA1 M1 domains away from the central axis of the channel during gating, which would thus limit dilation of the pore. Meanwhile, as the GluA2 subunits are not in direct contact with the JNJ-118 molecule they are freer to move. This may help explain why the drug reduces, rather than eliminates, the AMPAR response.
Our results add crucial detail to the understanding of JNJ-118’s action. NSFA revealed that JNJ-118 reduces the weighted mean single-channel conductance of γ8-containing receptors. Further, from direct resolution of single-channel events it was clear that the changes identified by NSFA reflected a decrease in the proportion of openings to the higher conductance sublevels. Given that the three conductance levels we identified match, respectively, the maximum conductance state O4 and sublevels O3 and O2 – produced when four, three or two LBDs contribute to gating (Coombs et al., 2017; Coombs and Cull-Candy, 2021) – our findings suggest that JNJ-118 simply reduces the probability that any individual AMPAR subunit will ‘gate’. Interestingly, although maximum conductance single-channel openings were less prevalent in the presence of the drug they were clearly still detectable. This would suggest that even when JNJ-118 is bound, all subunits are capable of contributing to gating. In turn, this suggests that the drug does not prevent expansion of the ‘gating ring’ (Yu et al., 2021), but rather reduces the extent of this expansion or the likelihood that it occurs.

The action of JNJ-118 contrasts, in certain key features, with that described for the anti-epileptic non-competitive AMPAR antagonist, perampanel. Perampanel binding sites are found on each GluA subunit (Yelshanskaya et al., 2016) and their occupancy renders the subunit unable to contribute to gating (Yuan et al., 2019). For example, when two perampanel molecules are bound, the receptor never produces O3 or O4 openings, and hence only opens to the lowest two conductance levels, while receptors occupied by four perampanel molecules are completely inhibited (Yuan et al., 2019). By contrast, JNJ-118 does not fully inhibit even GluA2/γ2.DM
receptors, which likely contain four TARPs and hence four binding sites (Hastie et al., 2013). Indeed, a small proportion of openings to the highest conductance level O4 are still seen. Interestingly, however, GluA2/γ2 peak currents were inhibited to a greater extent than those of GluA2/γ8, possibly reflecting differences in TARP stoichiometry.

**JNJ-118 reduces the functional impact of γ8 incorporation**

We found that while JNJ-118 application accelerated GluA2/γ8 deactivation and desensitization kinetics, decreased steady-state currents, decreased weighted mean conductance from NSFA, increased block by intracellular spermine, and decreased kainate efficacy, the effects were not sufficient to fully revert the properties to those of TARPlless AMPARs. Our data are thus consistent with the previous suggestion that several of the changes induced in AMPARs by JNJ-118 could result from a partial disruption of the interaction between γ8 and GluA subunits (Maher et al., 2016).

While the ability of JNJ-118 to reduce the proportion of single-channel openings to the higher conductance levels can be accounted for by restrictions placed on channel gating, the mechanism by which the drug accelerates deactivation kinetics and reduces the steady-state current is less apparent. TARP modulation of kinetic properties is generally viewed as an effect of the TARP’s first extracellular loop (Ex1) on the AMPAR LBD (Cais et al., 2014; Dawe and Bowie, 2016; Tomita et al., 2005; Turetsky et al., 2005), with additional influence from the TARP’s intracellular domains (Milstein and Nicoll, 2009; Turetsky et al., 2005). However, from cryo-EM images of hippocampal AMPARs bound to JNJ-118, it is difficult to determine how the drug might influence these LBD or the intracellular domain of the AMPAR (Yu et al., 2021).
As there is tight coupling between LBD closure and channel opening (Chen et al., 2017; Kristensen et al., 2011) it follows that while deactivation/desensitization is dictated by the LBD it will also be strongly influenced by the state of the gate. Therefore, the reduction in gating ring expansion seen in the presence of JNJ-118 (Yu et al., 2021) may well destabilize the open channel gate. This could accelerate deactivation and desensitization independent of any direct influence of JNJ-118 on the LBD.

Our observations on recovery from desensitization add further support to the idea JNJ-118 mediates functional changes by directly influencing the channel gate rather than the LBDs. Recovery from desensitization – the transition from the desensitized to the closed state – is the only property of GluA2/γ8 that we found to be unaltered by JNJ-118. Recovery from desensitization involves large rearrangements of the LBD dimers which are distant from the JNJ-118 binding site, but only very subtle rearrangements of the transmembrane regions which contain the drug binding site (Chen et al., 2017; Twomey et al., 2017). Thus, unlike channel activation, deactivation and desensitization, recovery from desensitization does not involve substantial movement (opening or closing) of the gate adjacent to the JNJ-118 binding site. Therefore, it is perhaps unsurprising that recovery from desensitization appears insensitive to JNJ-118.

**The accessibility of the JNJ-118 binding site**

We found no evidence that the gating state of the channel influenced JNJ-118’s ability to inhibit the currents. Thus, inhibition of open channels occurred within hundreds of milliseconds, and inhibition of closed channels was mostly complete...
after a single 200 ms application of JNJ-118, reaching equilibrium after two or three applications. This observation fits with recent structural information on the resting and active states of GluA1/GluA2/γ8/CNIH2 (Zhang et al., 2021), which revealed that, although gating transitions lead to expected rearrangements in the transmembrane domains, the JNJ-118 binding site is remarkably unchanged by activation.

We found that adding JNJ-118 to the intracellular solution occluded inhibition by extracellularly applied drug. This is of interest given that the JNJ-118 binding site, while found towards the extracellular side of the transmembrane regions (Yu et al., 2021; Zhang et al., 2021), appears from the cryo-EM structures to be less accessible from the extracellular space than it does from within the membrane. This raises the possibility that JNJ-118 could access its binding site through the membrane’s lipid phase even when applied from the outside.

The γ8-selective blockers represent an exciting development for the treatment of epilepsy. Most obviously, given their selective inhibition of forebrain AMPARs, they offer the promise of reduced motor side-effects (Kato et al., 2016; Maher et al., 2016; Zwart et al., 2014). However, the non-selective NAM perampanel, particularly at higher doses, additionally causes mood disturbance including depression and aggression (Ettinger et al., 2015; Villanueva et al., 2021). The action of JNJ-118 that we have identified – a reduction of single-channel conductance rather than a complete block – might suggest a further potential benefit of γ8-selective drugs. By producing partial inhibition of forebrain AMPARs, γ8-selective drugs such as JNJ-118 may enable a more nuanced intervention that could help to limit behavioral side-effects.

Table 1. Peak current block by JNJ-118 of GluA2 co-expressed with wild-type or mutated forms of γ8 and γ2.

Summary of peak current block ($I_{118}/I_{Ctrl}$), presented as mean ± s.d. from (n) patches.

To assess the extent of inhibition, one-sample Wilcoxon signed rank tests (against 100%) were used. For TARP effects, unpaired mean differences (upMD; GluA2+TARP vs GluA2 alone) with 95% confidence intervals [lower bound, upper bound] and p-values from Wilcoxon rank sum tests are shown. For pairwise tests, the p-values were adjusted for multiple comparisons using Holm’s sequential Bonferroni correction.

Fig 1. JNJ-118 decreases peak amplitude of currents from GluA2(Q)/γ8

a) Representative outside-out patch responses (10 mM glutamate, 200 ms, −60 mV) from two HEK293 cells transfected with GluA2/γ8 (left) or GluA2/γ8.DM (right) in control conditions (black) and in the presence of 1 μM JNJ-118 in both control and glutamate solutions (grey). Only the initial part of each response is shown, with the % peak current remaining in JNJ-118 indicated. b) Pooled peak inhibition data (\(I_{\text{JNJ-118}}/I_{\text{Control}}\)) showing the effect of 1 μM JNJ-118 on GluA2 alone, GluA2/γ8 and GluA2/γ8.DM. Box-and-whisker plots indicate the median (black line), the 25–75th percentiles (box), and the 10–90th percentiles (whiskers); filled circles are data from individual patches and open circles indicate means. Indicated p-values (adjusted for multiple comparisons as described in Table 1) are from two-sided Wilcoxon rank sum tests following a non-parametric omnibus test (Table S1).

Fig 2. JNJ-118 decreases the weighted mean channel conductance of GluA2(Q)/γ8

a) Representative outside-out patch responses (10 mM glutamate, 200 ms) (black bars) recorded at −60 mV from HEK293 cells transfected with GluA2/γ8 (left) or GluA2/γ8.DM (right) in control conditions (black) or in the presence of 1 μM JNJ-118 (grey). Insets show corresponding current-variance relationships and estimated channel conductance (\(\gamma\)) and peak open probability (\(P_{o,\text{peak}}\)). b) Scatter and paired plots showing the effects of 1 μM JNJ-118 on weighted mean channel conductance (\(\gamma\)) and \(P_{o,\text{peak}}\) values for GluA2, GluA2/γ8 and GluA2/γ8.DM. Open circles show individual values and filled circles denote the means, with error bars indicating s.e.m. In scatter plots dashed lines denote equality, with points below the lines indicating...
inhibitory effects of JNJ-118. Indicated p-values (adjusted for multiple comparisons as described in Table 1) are from two-sided Wilcoxon signed rank exact tests following a non-parametric omnibus test (Table S1).

Fig 3. JNJ-118 reduces the prevalence of higher conductance openings of GluA2(Q)/γ8 channels

a) Representative responses (10 mM glutamate, 200 ms; black bars) recorded at −60 mV from an outside-out patch expressing GluA2/γ8 in the presence and absence of 1 μM JNJ-118. Five consecutive sweeps are shown in each condition, the initial peak is truncated and the single-channel openings from these sweeps that were included in the analysis are highlighted. Note the prevalence of lower amplitude events in the presence of JNJ-118.

b) Pooled amplitude histograms of resolved GluA2/γ8 openings in the absence (top) and presence (bottom) of JNJ-118 (392 and 272 openings from 8 and 6 patches, respectively). Note the skew in amplitudes towards lower values in the presence of JNJ-118. Dotted black lines are individual gaussian fits with indicated means and proportions. Solid blue lines are the sums of the fitted gaussians.

Fig 4. JNJ-118 increases spermine block of GluA2(Q)/γ8 receptors

a) Representative responses evoked by 10 mM glutamate (200 ms; black bars) recorded at potentials between −110 mV and +80 mV from an outside-out patch in the absence (left) and presence (right) of 1 μM JNJ-118. In each case the responses at −60 and + 60 mV (from which RI was calculated) are shown in black.

b) Pooled normalized conductance-voltage relationships for GluA2/γ8 in the absence and presence of 1 μM JNJ-118. The filled symbols are the mean values from 6 cells (with
error bars showing s.e.m.) and the solid lines are fits of double Boltzmann relationships (see Methods). c) Scatter and paired plots (as in Fig 2) showing the effects of 1 μM JNJ-118 on Rectification Index and $V_b$ (from individual double Boltzmann fitted conductance-voltage relationships) for GluA2, GluA2/γ8 and GluA2/γ8.DM. The indicated p-values (adjusted for multiple comparisons as described in Table 1) are from two-sided Wilcoxon signed rank exact tests following a non-parametric omnibus test (Table S1).

**Fig 5. Inhibition by JNJ-118 is unaffected by channel state, and the drug is effective when applied intracellularly**

a) Representative concatenated responses from a GluA2/γ8 outside-out patch evoked by applications of 10 mM glutamate (200 ms, 1 Hz; black bars) at −60 mV, showing inhibition produced by pre-applications of 1 μM JNJ-118 (200 ms; grey bars). Right hand panel shows mean peak current data from 7 records (error bars indicate s.e.m.), normalized in each case to the mean of three applications delivered before the first pre-application of JNJ-118. b) Representative response from a GluA2/γ8 outside-out patch produced by a 48 s application of 10 mM glutamate (black bar) in the constant presence of 50 μM cyclothizide. Filled grey area denotes the rapid application of 1 μM JNJ-118 for 10 s. White dotted lines are single exponential fits showing the timecourse of block and unblock. c) Representative response, as in b, but recorded with an internal solution containing 10 μM JNJ-118. Note that in this case the extracellular application of JNJ-118 produced a greatly reduced block. d) Pooled data showing the degree of inhibition produced by 1 μM
JNJ-118\textsubscript{ext} when the internal solution contained either 0, 1 or 10 μM JNJ-118. Box-and-whisker plots as in Fig 1. Indicated p-values (adjusted for multiple comparisons using Holm's sequential Bonferroni correction) are from two-sided Wilcoxon rank sum tests following Kruskal-Wallis rank sum test (Table S1).

**Fig 6. A double point mutation in TARP γ2 introduces JNJ-118 sensitivity to GluA2(Q)/γ2**

a) Representative outside-out patch responses (10 mM glutamate, 200 ms) (black bars) recorded at −60 mV from HEK293 cells transfected with GluA2/γ2 (left) or GluA2/γ2.DM (right) in control conditions (black) or in the presence of 1 μM JNJ-118 (grey). Insets show corresponding current-variance relationships and estimated channel conductance (γ) and peak open probability (\(P_{o, \text{peak}}\)).

b) Pooled peak inhibition data (\(I_{JNJ-118}/I_{\text{Control}}\)) showing the effect of 1 μM JNJ-118 on GluA2 alone (from Fig 1b), GluA2/γ2 and GluA2/γ2.DM. Box-and-whisker plots as in Fig 1. Indicated p-values are from two-sided Wilcoxon rank sum tests (adjusted for multiple comparisons as described in Table 1) following a non-parametric omnibus test (Table S1).

c) Scatter and paired plots (as in Fig 2) showing the effects of 1 μM JNJ-118 on the weighted mean time constant of desensitization (\(\tau_{w, \text{des}}\)), the fractional steady-state component (\(I_{ss}/I_{\text{peak}}\)), the weighted mean channel conductance and \(P_{o, \text{peak}}\) values for GluA2/γ2 and GluA2/γ2.DM. Indicated p-values are from two-sided Wilcoxon signed rank exact tests (adjusted as described in Table 1) following a non-parametric omnibus test (Table S1).

d) Representative responses (10 mM glutamate, 200 ms; black bars) recorded at −60 mV from an outside-out patch expressing GluA2/γ2.DM in the presence and absence of 1 μM JNJ-118. Five consecutive sweeps are shown in each condition, the initial peak is truncated and selected single-
channel openings are highlighted. Note the prevalence of lower amplitude events in the presence of JNJ-118. e) Pooled amplitude histograms of resolved GluA2/γ2.DM openings in the absence (top) and presence (bottom) of JNJ-118 (228 and 289 openings from 2 and 3 patches, respectively). Note the skew in amplitudes towards lower values in the presence of JNJ-118. Dotted black lines are individual gaussian fits with indicated means and proportions. Solid blue lines are the sums of the fitted gaussians.

**Fig 7. JNJ-118 influences kainate relative efficacy but not recovery from desensitization**

a) Glutamate- and kainate-evoked currents (−60 mV) recorded from the same representative patch in the presence of 50 μM cyclothiazide, in the absence (left) and presence (right) of 1 μM JNJ-118. The glutamate responses are scaled to highlight the small decrease in the relative efficacy of kainate. b) Scatter and paired plots (as in Fig 2) showing the effects of 1 μM JNJ-118 on \(I_{KA}/I_{Glu}\) for GluA2, GluA2/γ8 and GluA2/γ2.DM. Indicated p-values are from two-sided Wilcoxon signed rank exact tests (adjusted for multiple comparisons as described in Table 1) following a non-parametric omnibus test (Table S1). c) Glutamate-evoked currents (−60 mV) from a representative GluA2/γ8 outside-out patch demonstrating the time course of recovery following desensitization with 10 mM glutamate (250 ms; black bar) in the absence and presence of 1 μM JNJ-118. Recovery of peak currents was assessed using glutamate re-application (10 ms; short black bars) at intervals from 2 – 500 ms, and single exponentials (dashed lines) were fitted to the peak currents. d) Scatter and paired plots showing the effects of 1 μM JNJ-118 on \(\tau_{rec}\) for GluA2, GluA2/γ8,
GluA2/γ8.DM, GluA2/γ2 and GluA2/γ2.DM. Open circles show individual values and filled circles denote the means, with error bars indicating s.e.m. In scatter plots dashed lines denote equality, with points below the lines indicating inhibitory effects of JNJ-118. Indicated p-values are from two-sided Wilcoxon signed rank exact tests (adjusted as described in Table 1) following a non-parametric omnibus test (Table S1).
