ABSTRACT

Regulators of G protein signaling (RGS) proteins modulate G-protein coupled receptor (GPCR) signaling by acting as negative regulators of G proteins. Genetic variants in RGS proteins are associated with many diseases, including cancers, although the impact of these mutations on protein function is uncertain. Here we analyze the RGS domains of 15 RGS protein family members using a novel bioinformatic tool that measures the missense tolerance ratio (MTR) using a three-dimensional (3D) structure (3DMTR). Subsequent permutation analysis can define the protein regions that are most significantly intolerant (P<0.05) in each dataset. We further focused on RGS14, RGS10, and RGS4. RGS14 exhibited seven significantly tolerant, and seven significantly intolerant residues; RGS10 had six intolerant residues; and RGS4 had eight tolerant and six intolerant residues. Intolerant and tolerant-control residues that overlap with pathogenic cancer mutations reported in the COSMIC cancer database were selected to define the functional phenotype. Using complimentary cellular and biochemical approaches, proteins were tested for effects on GPCR-Gα activation, Gα binding properties, and downstream cAMP levels. Identified intolerant residues with reported cancer-linked mutations RGS14-R173C/H and RGS4-K125Q/E126K, and tolerant RGS14-S127P and RGS10-S64T resulted in a loss-of-function phenotype in GPCR-G protein signaling activity. In downstream cAMP measurement, tolerant RGS14-D137Y and RGS10-S64T, and intolerant RGS10-K89M resulted in change of function phenotypes. These findings show that 3DMTR identified intolerant residues that overlap with cancer-linked mutations cause phenotypic changes that negatively impact GPCR-G protein signaling and suggests that 3DMTR is a potentially useful bioinformatics tool for predicting functionally important protein residues.

Significance Statement Human genetic variant/mutation information has expanded rapidly in recent years, including cancer-linked mutations in RGS proteins. However, experimental testing of the impact of this vast catalogue of mutations on protein function is not feasible. We used the
novel bioinformatics tool 3DMTR to define regions of genetic intolerance in RGS proteins and prioritize which cancer-linked mutants to test. We found that 3DMTR more accurately classifies loss-of-function mutations in RGS proteins than other databases thereby offering a valuable new research tool.

**Keywords**: RGS proteins, G proteins, GPCR, cancer mutations, genetic variance, 3DMTR
1. INTRODUCTION

Since the publication of the human genome and the development of bioinformatic sequencing tools, human genetic variant information is being identified rapidly. These advances led to the creation of many publicly available databases that reflect both healthy and diseased human populations. However, experimental testing of the vast catalogue of identified mutations is simply not feasible. Missense mutations are genetic variations where a single base pair substitution produces a different amino acid at the same position. Variations in protein structure can affect folding, stability and aggregation, thereby affecting the function of signaling proteins (Thusberg and Vihinen 2009). Functionally relevant genetic variation has been reported in many proteins, including the regulators of G-protein signaling (RGS) (Squires et al. 2021).

RGS proteins play a vital role modulating G Protein Coupled Receptor (GPCR)-G protein signaling events. All RGS proteins share an evolutionary conserved RGS domain that binds active Gα subunits and acts as GTPase accelerating proteins (GAPs), negatively regulating GPCR-Gα signaling (Tesmer et al. 1997; Hollinger and Hepler 2002; Willars 2006). Outside of their GAP function, RGS proteins competitively bind active Gα and receptors to promote the rapid cycling of Gα subunits between active and inactive states (McCoy and Hepler 2009).

Recent deep sequencing studies have shown GPCR-G protein complexes to be frequently mutated in cancer (DiGiacomo et al. 2020; Kan et al. 2010; O'Hayre et al. 2013). GPCRs are expressed in cancerous tissues and mediate proliferation, survival, invasion, and metastasis (Gutkind 1998; Hurst and Hooks 2009). The pro-oncogenic effects of overexpressed constitutively activating mutations in GPCRs (DiGiacomo et al. 2020; Moore et al. 2016; O'Hayre et al. 2013; Wright et al. 2019) and Gα subunit, (DiGiacomo et al. 2020; Ideno et al. 2018; Nairismagi et al. 2016; Van Raamsdonk et al. 2009; Van Raamsdonk et al. 2010; Wu et al. 2011) have led to enhanced downstream signaling in reported cancer studies. Cancer-derived activated mutations in Gαo can induce oncogenic transformation (Garcia-Marcos, Ghosh, and Farquhar 2011), while inactivated mutations in Gai/o-receptors can lead to
enhanced cAMP activity (Chaudhary and Kim 2021). These studies suggest that the loss of Ga binding and GAP function in RGS proteins can promote oncogenic activity.

Multiple sequence-based analytical tools provide information and predictions about evolutionary conserved areas of a protein that are vital for structure and function (Nobrega and Pennacchio 2004). Interestingly, sequence-based tools, like missense tolerance ratio (1DMTR) (Traynelis et al. 2017) and SIFT, access the same genetic variant databases to run their algorithms but interpret the predictive effect of a mutation in different ways. Recently, a novel tool known as 3DMTR permutation analysis (3DMTR) (Perszyk et al. 2021) has been developed but not yet widely tested. The improved 3DMTR algorithm calculates the missense tolerance ratio for the neighboring residues in three-dimensional (3D) distance from protein crystallography or cryo-EM data.

RGS proteins are divided in subfamilies based on sequence homology and other shared domains (Stewart and Fisher 2015; Hepler 1999; Willars 2006; Sjogren and Neubig 2010). Here we analyzed the RGS domains of 15 RGS proteins with reported structures, and focused on assessing three RGS proteins in particular: RGS14, RGS10 and RGS4. RGS14 and RGS10 are members of the D/R12 family. RGS14 is a complex multidomain signaling molecule selective for Gαi/o (Cho et al. 2000; Vellano et al. 2011) and is highly expressed in brain regions essential for learning and memory (Harbin et al. 2021). RGS10 is a smaller molecule that selectively binds Gαi/o members (Hunt et al. 1996; Popov et al. 1997; Watson et al. 1996). In contrast to RGS14, RGS10 is broadly expressed making it an essential regulator of physiological processes including inflammatory responses and survival signaling (Alqinyah et al. 2018). Much smaller than RGS14, RGS4 is part of the R4 subfamily and is highly expressed in brain where it has been linked to psychiatric disorders(Terzi et al. 2009; Schwarz 2018), and in opioid reward and addiction (Sakloth et al. 2020). RGS4 is selective for Gαi/o and Gαq members (Hepler et al. 1997; Tesmer et al. 1997), preferring signaling by Gαi/o over Gαq in a neuronal model (Masuho et al. 2020).
In the present study, we carry out a functional assessment of the predictive capabilities of the novel 3DMTR applied to RGS proteins. We combine this with available somatic mutational information found in cancer samples to determine the effect these genetic variants will have on RGS14/10/4 protein structure and function. We test how cancer mutations in significant regions of the protein can lead to changes in RGS function assessed by various cell based and biochemical assays.
2. MATERIALS AND METHODS

2.1 Three-dimensional missense tolerance with permutation analysis (3DMTR)

The 3DMTR permutation analysis was performed as described (Perszyk et al. 2021). To perform 3DMTR analysis on RGS protein structures, the encapsulated application MATLAB (Mathworks, version R2019b), available on GitHub (https://github.com/riley-perszyk-PhD/3DMTR, current version v2.000) was used. The protein structures of the analyzed RGS proteins were obtained from the Protein Data Bank (rcbs.org). Reference of all the crystal structures used is available in the supplementary section Table 1 (Supp. Table 1). Variant datasets of all RGS genes were downloaded from the Genome Aggregation Database (gnomAD) website (https://gnomad.broadinstitute.org/, version 2.1.1). The translated coding gene sequences of RGS proteins were used (RGS1, NM_002922.4; RGS2, NM_002923.4; RGS3, NM_144488.6; RGS4, NM_001102445.2; RGS5, NM_003617.4; RGS6, NM_001204416.3; RGS7, NM_001282773.2; RGS8, NM_033345.3; RGS9, NM_001081955.3; RGS10, NM_001005339.2; RGS12, NM_002926.3; RGS14, NM_006480.5; RGS16, NM_002928.4; RGS17, NM_012419.5; RGS18, NM_130782.3). The closest 21 residues were used in the 3DMTR calculations since the RGS protein domain structures are small (~120 residues) to provide more stratified scores. Permutation analysis was preformed using 1000 iterations by randomizing the residue location. Permutation significance was determined where the 3DMTR score was outside the 2xSTD range (permutation standard deviation of each residue) calculated from the permutation mean score for each residue. We define the residues that are identified with permutation analysis as either significantly intolerant or significantly tolerant depending on which tail of the permutation distribution they fall within. Additionally, having an MTR score of < 0.5 is very rare (the 5%ile score for the 1DMTR is 0.5462, http://mtr-viewer.mdhs.unimelb.edu.au/). Previous work suggests that the 3DMTR and the 1DMTR generally produce a similar set of MTR scores, albeit the scores are rearranged based on the different selection criteria, so we believe this cut off is also appropriate for the 3DMTR scores.
Thus, we deem the residues with 3DMTR scores ≤0.5 as being important and will call highly intolerant.

2.2 Cell culture and reagents

Human embryonic kidney (HEK) 293 cells were cultured in 1X Dulbecco’s Modified Eagle’s Medium (DMEM), without phenol red indicator, supplemented with 10% fetal bovine serum (FBS), 2mmol/L L-glutamine, 100 units/mL penicillin, and 100 mg/mL streptomycin. HEK cells were kept in a humidifier incubator with 5% CO₂ at 37°C. Trypsin-EDTA 0.25% was used during cell culture procedures. Cells were seeded 8x10⁵ in 2 mL of transfection medium per well in six-well plates. Transfection media was formulated with 5% FBS in DMEM phenol-red free media and polyethyleneimine (PEI) was the transfection agent used.

The Hemagglutinin (HA) epitope-tagged α2a-adrenergic receptor (HA-α2a-AR) construct was kindly provided by Dr. Joe Blumer (Medical University of South Carolina). The G protein used in our studies were Glu-Glu tagged Gαo (Gαo-EE) and the pertussis-resistant mutant C351G of Gαo (Gαo-CG) which was purchased from the cDNA Resource Center (cDNA.org, Bloomsberg, PA). Mas-GRK3ct-Luc and Ven-Gβγ were described previously (Hollins et al. 2009). Human Flag-tagged RGS14 (Flag-RGS14 WT), human Flag-RGS14-S127P, human Flag-RGS14-D137Y, human Flag-RGS14-R173C, human Flag-RGS14-R173H, human Flag-tagged RGS10 wildtype (Flag-RGS10 WT), human Flag-RGS10-S64T, human Flag-RGS-K89M, hemagglutinin epitope-tagged rat RGS4 wildtype (HA-RGS4 WT), rat HA-RGS4-K125Q, rat HA-RGS4-E126K, rat HA-RGS4-E135K were generated as previously described (Bernstein et al. 2004; Shu et al. 2007). Pertussis toxin #181 was purchased from List Biological Laboratories, Inc (Campbell, CA). UK 14,304 was obtained from Sigma-Aldrich (U104, St. Louis, MO). Forskolin was obtained from Sigma-Aldrich (F6886, St. Louis, MO).
2.3 Kinetic Bioluminescence Resonance Energy Transfer (BRET)

Kinetic BRET experiments were performed as previously described (Brown, Lambert, and Hepler 2016; Lambert et al. 2010). After a 48 hr transfection, cells were resuspended in Tyrode’s solution (140 mmol/L NaCl, 5 mmol/L KCl, 1 mmol/L MgCl₂, 1 mmol/L CaCl₂, 0.37 mmol/L Na₂HPO₄, 24 mmol/L NaHCO₃, 10 mmol/L HEPES, and 0.1% glucose, pH 7.4) and plated on white 96-well Optiplates (Perkin Elmer Life Sciences, Waltham, MA). Fluorescence measurements were made using the TriStar LB 941 plate reader (Berthold Technologies, Bad Wildbad, Germany) with 485-nm excitation and 530-nm emission filters to confirm acceptor expression. After a 10 min application of 5 μmol/L coelenterazine H (Nanolight Technologies, Pinetop, AZ), in vivo kinetic BRET was recorded using sequential measurements through 485- and 530-nm emission filters. BRET was recorded for 30 seconds with no stimulation to establish basal BRET. After 30 seconds of basal BRET recording, α₂A-adrenergic receptor agonist UK 14,304 (100μM) was injected into the cells. The presence of the agonist induces Gα protein activation and the change in BRET is calculated by dividing the mas-GRK3ct-Luc signal (530 nm) by the Ven-Gβγ signal (485 nm) and subtracting the average BRET signal observed from the first 30 seconds of observation (basal BRET). With each experiment, a kinetic BRET control was performed using pertussis insensitive Gαo. Pertussis toxin was added to the transfection media to all wells. Any BRET signal recorded in the control wells transfected with pertussis sensitive Gαo was regarded as noise and subtracted from experimental kinetic BRET recordings. Data was collected using the MikroWin 2010 software (Mikrotek Laborsysteme GmbH, Overath, Germany) and analyzed using Microsoft Excel and GraphPad Prism 9.

2.4 Co-immunoprecipitation of RGS and Gαo

After a 24 hours transfection, HEK cells were washed three times with cold 1X PBS. Cells were scraped into AMF lysis buffer (50 mM Tris, 150 mM NaCl, 1 mM EDTA, 2 mM DTT,
10 mM NaF, 14 mM MgCl₂, 10 mM AlCl₃, 1X Roche protease inhibitor, 1X Halt phosphatase inhibitor) and lysed at 4°C for one hour while rotating end-over-end. Lysates were cleared by centrifuging at 13000 RPM for 10 min at 4°C. For each condition, 50 uL of affinity gel beads were used. Anti-FLAG M2 affinity gel (Sigma A2220) was used to immunoprecipitated Flag-RGS14 and Flag-RGS10, while monoclonal anti-HA agarose beads (Sigma A2095) was used for HA-RGS4 immunoprecipitations. Affinity gel beads were washed three times with cold 1X PBS and then blocked with 4% BSA in PBS at 4°C for one hour while rotating end-over-end. Cleared cell lysate was collected for input, and the remaining lysate was added to blocked anti-FLAG M2 affinity beads or anti-HA agarose beads. Immunoprecipitation of Flag-tagged RGS from lysate was performed at 4°C for two hours while rotating end-over-end, while HA-tagged RGS was performed overnight. After immunoprecipitation, the beads-RGS complex was washed three times with cold 0.1% Tween-20 in PBS. Input and immunoprecipitated samples were denatured by boiling in Laemmli buffer for 5 min.

### 2.5 Analysis of immunoblots

Denatured cell lysate samples in Laemmli Buffer were resolved on 13.5% SDS-PAGE, and samples were then transferred to nitrocellulose membranes. Membranes were blocked in 5% non-fat milk for one hour at room temperature. For FLAG-tagged RGS (RGS10 WT and mutants, or RGS14 WT and mutants.), HRP-conjugated anti-FLAG antibody (Sigma A8592, 1:15,000) was diluted in TBS/T and incubated with the membranes for 45 minutes at room temperature. For HA-tagged RGS4 and mutants, Anti-HA-Peroxidase rat monoclonal antibody (Roche Cat# 12013819001, 1:5000) diluted in TBS/T was used. For Gαo, anti-EE (Covance MMS-115R, 1:1000) was diluted in 5% non-fat milk and incubated with membranes overnight at 4°C. HRP-conjugated goat anti-mouse IgG secondary antibody (Jackson ImmunoResearch 115-035-003, 1:5000) was diluted in TBS/T and incubated with membranes for 45 minutes at
room temperature. Blots were developed using ECL and imaged using the ChemiDoc MP Imaging system (BioRad).

2.6 GloSensor™ cAMP assay

To measure intracellular cAMP levels, we used the GloSensor™ cAMP assay. The cAMP GloSensor™ was obtained from Promega and the assay was performed following the manufacturer’s instructions (Promega, Madison, WI, USA). HEK293 cells were harvested (15,000 cells per individual well) in tissue culture-treated 96-well flat bottom plate. Cells were kept in 37°C tissue culture incubator 5-10% CO2 overnight. Cells were transfected with 50ng of pGloSensor-20F cAMP, 50ng α2-AR, 50ng RGS of interest, and pcDNA in DMEM serum free media. After 24 hours, the media is removed without disrupting the cell monolayer and 100μL of the equilibrium medium is added (2% v/v dilution of the GloSensor cAMP Reagent stock solution). Incubation with the equilibration reagent is done for 2 hours and cells are kept in 37°C tissue culture incubator 5-10% CO2 in the dark. After 2 hours, basal luminescence intensity was measured at 0 and at 5 minutes using a luminometer (FLUOstar) in triplicates. To measure α2-AR-Gαi/o directed inhibition of cAMP, cells are pre-incubated with 100 μL of 100 μM UK14,304 (agonist) or DMSO (vehicle) in HBSS for 10 minutes at room temperature following basal readings. At 10 minutes, cAMP production is stimulated by adding 10μM forskolin and luminescence is measured every 5 minutes for a total of 50 minutes. The data in relative light units (RLU) from triplicates wells were averaged and a response over time graph is generated. Normalization was done by dividing each time point following forskolin stimulation over basal luminescence, then each time point is divided by empty vector (50ng pcDNA alone) control. Area under the curve for each condition is calculated and the effect of the mutants is compared to the WT RGS effect in Gαi/o-coupled α2-AR stimulation of cAMP.
2.7 Data analysis and statistics

Data analysis was conducted using Microsoft Excel and GraphPad Prism 9 software. Kinetic BRET activation curves were presented as a mean of 3 or 4 experimental replicates. We then selected the maximum BRET amplitude at 100 seconds for each condition. Maximum BRET amplitude columns were compared by performing a statistical analysis using one-way analysis of variance (ANOVA) with Dunnett’s test. Luminescence-based cAMP GloSensor assay relative light units (RLU) were recorded from averaged replicate wells and plotted as response over time, with a total of 4 experimental replicates. We then analyzed the area under the curve (AUC) for each condition and columns were statistically analyzed using one-way analysis of variance (ANOVA) with Dunnett’s test.
3. RESULTS

3.1 3DMTR predicts amino acid residues in RGS proteins likely to be intolerant to mutation

RGS proteins share an evolutionary conserved ~120 amino acid RGS domain that binds activated G protein alpha subunits to act as GAPs. In this study, we examined the canonical human RGS proteins using a bioinformatic tool that evaluates the degree of variation that exists in the gnomAD database (large database of human whole exomes and genomes of healthy individuals) and determines a composite score, missense tolerance ratio (MTR) (Traynelis et al. 2017). This MTR score is determined based on the location of the linear polypeptide chain (1DMTR; Traynelis et al. 2017). A newly described bioinformatics tool expands on this idea to measures MTR based on the location of each residue in three-dimensional (3D) space (3DMTR; Perszyk et al. 2021) based on reported protein crystallography or cryo-EM data. This 3DMTR is a more accurate and improved bioinformatic tool that also utilizes a permutation analysis to calculate the relative significance of the missense tolerance ratio of a given dataset (Perszyk et al. 2021). Both 1DMTR and 3DMTR use available human variation data from neighboring residues to report population level genetic variation and measures the tolerance ratio within the entire genome.

A comparison of the 1DMTR and the 3DMTR analysis for the RGS domain of one representative RGS protein, RGS14, is shown as scatter plots in Fig. 1A and Fig. 1C. In a previous report (Squires et al. 2021), we described in detail the 1DMTR results for RGS proteins. Considering the RGS domain of RGS14 (Fig. 1A), the 1DMTR analysis of the RGS domain generally shows more tolerant scores (0/134 residues have 1DMTR scores ≤0.5), which are shown as red shades superimposed onto the RGS domain structure (Fig. 1B). Structural data has been reported for the RGS domain of most RGS proteins, including RGS14 (Soundararajan et al. 2008). Using this information, we analyzed the RGS domains of 15 of 20 RGS protein family members, including RGS14, using the 3DMTR analysis (Supp. Fig. 1) as will
be discussed further below. In contrast to 1DMTR, the 3DMTR uses the same human variation data but instead utilizing the neighboring residues in 3D space, which should be functionally more relevant to determine the tolerance ratio.

We analyzed the RGS domain of RGS14 by 3DMTR (Fig. 1C and D). Because the size of RGS domains (~120 aa) are much smaller than the entire RGS proteins (~200-1400 aa), the 3DMTR was calculated using the nearest 21 residues instead of the 31-residue window that has been used for larger proteins. Based on this, the 3DMTR may be a more accurate predictor of highly intolerant residues compared to the 1DMTR. We will refer to the residues that appear to have selective pressure controlling their variation as ‘highly intolerant’ (3DMTR score of ≤0.5). The 3DMTR analysis of the RGS domain of RGS14 identified several residues with highly intolerant scores (7/134 residues have 3DMTR scores ≤0.5, Fig. 1C), shown in blue shades superimposed onto the RGS domain structure (Fig. 1D). Furthermore, we used permutation analysis that determines which residue scores are highly unlikely given a specific dataset (occurring in less than 5% of random permutations). It can be interpreted that the residues identified by permutation analysis that are either significantly intolerant or significantly tolerant, i.e. those that would be unexpected within each analyzed dataset (consisting of the gene sequence, protein structure, and gnomAD dataset). Primarily of note, the analysis suggests that the significantly intolerant residues may relatively (compared to the rest of the residues in the protein) have selective pressures that limit variation in these regions. The permutation analysis of RGS14 (Fig. 1E) identified 14 residues that were significantly intolerant, whereas 3.4 would have been expected randomly given the dataset (based on the expected frequencies of a single tail of a normal distribution using α equal to 0.05, 0.025 * 134 residues). Comparing the 1DMTR and 3DMTR data for RGS14, the 3DMTR analysis of the RGS domain of RGS14 predicts highly intolerant residues not found with the 1DMTR (0 with 1DMTR vs 7 with 3DMTR, total residues 134, Fisher’s exact test p = 0.0144). The permutation analysis of RGS14 (Fig. 1E) identified 14 residues significantly intolerant, 7 residues highly intolerant (3DMTR score ≤0.5) and 7 tolerant.
(not highly intolerant) (3DMTR score >0.5). The significantly intolerant residues are visualized in blue on the structure of the RGS domain of RGS14 (Fig. 1F).

Next, each RGS domain of all available structures for RGS protein family members were analyzed using 3DMTR (Fig. 2, Supp. Fig. 1). For this analysis, we utilized the reported structures of RGS protein domains that are available for 15 of the 20 RGS proteins (Supp. Fig. 1). Interestingly, each RGS domain presented a distinct “bar code” of significantly intolerant and significantly tolerant residues (Fig. 2 and Supp. Fig. 1). A second 3DMTR analysis was performed on four RGS protein domains in complex with active forms of their Gα partners (Supp. Fig. 2: RGS1-Gαi1, RGS4-Gαi1, RGS10-Gαi3 and RGS16-Gαi1). In each of these cases, the profiles for significantly tolerant and intolerant residues differed slightly by active Gα binding.

We next compared the 3DMTR results for RGS14, RGS10 and RGS4. These three RGS proteins were chosen because of their involvement with various cancers and their differences in size and structure. Raster plots for RGS14 (Fig. 2A), RGS10 (Fig. 2B), and RGS4 (Fig. 2C) show the comparison of 1DMTR data with 3DMTR data calculated using the nearest 21 or 31 residues, as before. For each, tolerant (red) or significantly intolerant (blue) residues are shown (c21-sig). The 3DMTR analysis predicts intolerant residues not found with the 1DMTR analysis. As observed with the other RGS proteins (Supp. Fig. 1), the RGS domains of RGS14, RGS10, and RGS4, each presented a distinct “bar code” of significantly intolerant residues (Fig. 2 and Supp. Fig. 1-2).

As was the case for RGS14 (Fig. 1 and Fig. 2A), 3DMTR predicted for RGS10 more highly intolerant scores than 1DMTR (Fig. 2B) (1 with 1DMTR vs 7 with 3DMTR, total residues 136, Fisher’s exact test p = 0.0663) and for RGS4 (Fig. 2C) (1 with 1DMTR vs 6 with 3DMTR, total residues 128, Fisher’s exact test p = 0.1199). The structure of each of the RGS domains is shown with significantly tolerant and intolerant residues highlighted in red and blue, respectively (Fig. 2D-2I). Each is shown bound to the reported structure of Gai1 (Fig. 2D and 2F), Gai3 (Fig.
2E), or alone (Fig. 2G-2I). Comparison of the three RGS domain structures in the same orientation with the intolerant residues highlighted in blue (Fig. 2G-I), shows that these residues are distributed differently within the domain structure. We next performed permutation analysis for the RGS domains of RGS10 and RGS4 (Supp. Fig. 3) and compared those to RGS14 (Fig. 1E).

The amino acid sequence for each of these RGS proteins are aligned (Fig. 2J). The RGS domain is highlighted in lilac, in gray are the residues that directly interact with Ga, and in orange the residues that are in the hydrophobic core (Tesmer et al. 1997). The significant residues identified by the permutation analysis are identified with symbol under each residue letter, * for the identified residues that were also highly intolerant (MTR ≤0.5) and ^ for identified residues that were not highly intolerant residues (MTR >0.5). As shown in Fig. 2J, the profiles of intolerant residues differ across each protein. 3DMTR identified highly intolerant residues found in the RGS hydrophobic core were residue F81 in RGS14, and I93 and F97 in RGS10. 3DMTR identified highly tolerant residues in RGS4 F91, W92 and I114 are also found in the hydrophobic core. Intolerant residues in the direct contact with G alpha in RGS14 are N93 and R173, and tolerant residues are RGS14-D137 and RGS4 E87 and N88. Compared with the permutation analysis for RGS14 (Fig. 1E), the same analysis of RGS4 identified 15 significantly intolerant residues, whereas 3.2 would have been expect randomly given the 128-residue dataset. The permutation analysis of RGS10 identified 5 residues that were significantly intolerant, whereas 3.4 would have been expected randomly given the 136-residue dataset.

We next focused on the significantly intolerant or tolerant residues in RGS14, RGS10 and RGS4 identified by the 3DMTR analysis that overlap with reported somatic pathogenic mutations found in patient cancer samples identified in the Catalogue of Somatic Mutations in Cancer (COSMIC) database (Table 1). Using various in vitro assays of RGS-G protein interaction and signaling, we test the effect of an amino acid change, due to cancer mutations, in the selected significant residues and how these affect canonical RGS function.
3.2 Reported pathogenic somatic mutations in RGS14, RGS10 and RGS4 that overlap with residues identified by 3DMTR to be significantly intolerant to mutation

Several bioinformatics tools (discussed below) that estimate the pathogenic potential of reported human somatic mutations are publicly available. Cells can develop somatic mutations due to imperfect replication or exposure to endogenous and exogenous mutagens (Olafsson and Anderson 2021). Most somatic mutations will have little or no phenotypic effect, whereas a small minority of mutations can affect protein function and cell physiology leading to the progress of complex diseases (Olafsson and Anderson 2021). These mutations occur post-zygotically and exist in a subpopulation of cells (Dou et al. 2018). Online databases like COSMIC (cancer.sanger.ac.uk/cosmic) report somatic mutations found in human cancers. COSMIC uses a FATHMM-MKL algorithm to predict the functional, molecular and phenotypic consequences of proteins missense variants using Markov models classifying the mutations as pathogenic (scores≥ 0.7) or neutral (≤ 0.5)(Shihab et al. 2015)(Tate et al. 2018). Using these tools, we identified somatic mutations that overlap with residues in the RGS domain of RGS14, RGS10 and RGS4 identified by the 3DMTR to be either more sensitive or less sensitive to mutations (Supp. Tables 2-4).

RGS14 has been reported to be highly expressed in liver cancer and glioma (Uhlen et al. 2017). The analysis of The Cancer Genome Atlas (TCGA) and Gene Expression Omnibus (GEO) datasets have identified RGS14 as one of the five-gene signature biomarkers for Glioblastoma for Glioblastoma multiforme (GBM) (Yin et al. 2019). Somatic mutations in RGS14 that overlap with residues predicted to be highly tolerant or intolerant by the 3DMTR are shown in Supp. Table 2. Mutations found in RGS14 of patient samples with large intestine carcinoma include R173C, R173H, and S170R. RGS14 somatic mutation S127P is found in gastroesophageal junction carcinoma, and D137Y is found in prostate carcinoma. Of note, coding silent mutations in RGS14 and other RGS proteins are also reported to overlap with significant residues
identified by 3DMTR. For RGS14 these are residues N93, A99 and R173, and are included because the COSMIC FATHMM-MKL algorithm surprisingly and inexplicably designated some of these silent mutations to be pathogenic. Residues in RGS14 scored by the 3DMTR >0.05 and overlap with somatic mutations considered pathogenic by the COSMIC algorithm are S127P and D137Y. Residues scored by the 3DMTR ≤0.05 and predicted to be pathogenic are S170R, R173C, R173H, and coding silent R173.

RGS10 has been reported to be highly expressed in renal, endometrial, and cervical cancer (Uhlen et al. 2017). This ubiquitously express protein regulates physiology and signaling pathways in microglia, macrophages, T-lymphocytes, neurons, osteoclasts, cardiomyocytes, platelets, and cancer cells. It has been identified as an important regulator of cell survival and chemoresistance (Cacan et al. 2014; Hooks et al. 2010) and transcript expression is significantly suppressed in multiple ovarian cancer cell lines (Ali et al. 2013; Cacan et al. 2014). Moreover RGS10 acts as a tumor suppressor by blunting endogenous survival pathways (Cacan et al. 2014), and has been reported to regulate inflammatory signaling pathways in ovarian cancer cell survival (Alqinyah et al. 2018). Somatic mutations in RGS10 that overlap with residues deemed to be highly tolerant or intolerant by the 3DMTR are shown in Supp. Table 3. Mutations found in RGS10 of patient samples with lung carcinoma are S64T and coding silent A73, while K89M can be found in thyroid carcinoma samples.

Studies have shown association between RGS4 and enhanced cell viability, invasion and motility in thyroid cancer (Nikolova et al. 2008), glioma (Tatenhorst et al. 2004; Weiler et al. 2013), ovarian cancer (Puiffe et al. 2007), and triple negative breast cancer (Xie et al. 2009). Somatic mutations in RGS4 that coincide with 3DMTR identified significant residues (Supp. Table 4) are found in carcinoma samples of the following tissues: large intestine E87D, thyroid I89N, kidney W92C, endometrium K113N, breast Q122H and A123E, stomach A123T, and lung K125Q. Overlapping mutants were also found in melanoma including E126K, E135K, and silent coding F118 and V127 in RGS4.
Based on these findings, we chose to study selected somatic mutations in RGS14, RGS10 and RGS4 that overlap with residues identified by 3DMTR to be either tolerant or intolerant to mutation. Our goal for these studies was to test how well 3DMTR and other bioinformatic tools predict important residues for protein function and pathogenic potential. These specific residues and somatic mutations chosen for further study are listed in Table 1. Mutations in RGS14 selected for study were S127P, D137Y, R173C, and R173H (Fig. 3). Mutations in RGS10 selected for further study are amino acid mutation S64T and K89M (Fig. 4). Mutations in RGS4 chosen for further study were K125Q, E126K, and E135K (Fig. 5).

3.3 Assessment of somatic mutations in 3DMTR-identified tolerant and intolerant residues in GPCR/G protein activation and G protein binding

RGS14 is a member of the D/R12 subfamily and contains an RGS domain as well as accessory domains that play a role in different signaling pathways such as the tandem Ras/Rap-binding domains (R1 and R2), a G protein regulatory (GPR) motif, and a C-terminal PDZ binding motif (Cho et al. 2000; Traver et al. 2000; Hollinger et al. 2001; Hollinger and Hepler 2002; Shu et al. 2007; Vellano et al. 2013; Zhao et al. 2013; Friedman et al. 2022). We first examined the effects of mutational changes in 3DMTR-defined tolerant and intolerant residues on RGS14 functions (Fig. 3). For these and subsequent studies (Figs. 4 and 5), we utilized a live cell biosensor (BRET) assay to measure RGS effects on GPCR/G protein activation (Brown, Lambert, and Hepler 2016). HEK293 cells were transfected with α2A-adrenergic receptor (α2AR), Gαo, Gβ1-venus, Gγ2-venus, and the biosensor for Gβγ binding mas-GRK3ct-Luc, as previously reported (Brown, Lambert, and Hepler 2016). Upon addition of α2AR agonist UK 14,304 (100μM), GPCR signaling is activated leading to the dissociation of Gα and Gβγ-venus. The Gβγ-venus binds to the mas-GRK3ct-Luc biosensor resulting in an increase in BRET signal (Hollins et al. 2009). Using this model (Fig. 3A) we can test the effects of RGS mutants in α2-adrenergic receptor-Gαo protein activation.
RGS4, RGS10 and RGS14 each bind to active Ga\(i/o\) protein family members including Goo1, Goo2, Gai1, Gai2, and Gai3 (Masuho et al. 2020). Of these, Goo is the most indiscriminate G alpha protein, is regulated by all canonical RGS proteins (Masuho et al. 2020), and its highly expressed in the brain where it couples \(\alpha_2\)AR (Goldenstein et al. 2009; Nobles, Benians, and Tinker 2005). Our previous studies compared \(\alpha_2\)AR G-protein activation with Goo and Gai1, and Goo provided a much more robust maximum BRET amplitude signal (Brown, Lambert, and Hepler 2016). For these reasons, we employed a live cell \(\alpha_2\)AR-Goo model to test the effects of RGS protein mutants in G protein activation.

Using the above assay, we examined the effects of selected somatic mutations on RGS14 capacity to regulate receptor-G activation (Fig. 3). Four mutations were tested including two which were scored by 3DMTR-permutation analysis as tolerant (S127P and D137Y) (Fig. 3C-3F) and two as intolerant (R173C and R173H) (Fig. 3G-3J). Wild type RGS14 and mutant proteins expressed well in HEK 293 cells (Supp. Fig. 4A). The relative position of these residues within the RGS domain structure are shown in Fig. 3B highlighted as either red (tolerant) and blue (intolerant). As shown in Figures 3C-3D and 3E-3F, somatic mutations within the tolerant residues exhibited distinct phenotypes. Whereas mutant D137Y behaved as expected (i.e., like wild type RGS14) to inhibit agonist activation of \(\alpha_2\)AR-Goo (Fig. 3E-3F), mutant S127P exhibited a loss-of-function (LoF) phenotype (Fig. 3C-3D). In examining the two somatic mutations found in intolerant residue R173 of RGS14, both R173C (Fig. 3G-3H) and R173H (Fig. 3I-3J) behaved as expected with both mutations exhibiting a LoF phenotype. In parallel, we assessed direct binding of each RGS14 mutation with active Goo as measured by affinity capture by immunoprecipitation from HEK293 cell lysates treated with AlF\(_4^{-}/Mg^{++}\) (AMF) to activate cellular G proteins including of Goo (Fig. 3K). We observed that the direct binding properties of the mutants mirrored that for RGS regulation of \(\alpha_2\)AR-Goo activation. Specifically, mutant D137Y bound active Goo, whereas mutants S127P, R173H and R173P all failed to bind.
Gαo (Fig. 3K). In summary, 3 of the 4 somatic mutations found in tolerant and intolerant residues of RGS14 as defined by 3DMTR behaved as predicted.

RGS10 is also part of the R12 subfamily, however, it is one of the smallest proteins in the RGS family and shares only a single conserved RGS domain in common with RGS14 and RGS12. Next, we examined the effects of selected somatic mutations on RGS10 functions using the same assay systems as described above (Fig. 4). In the case of RGS10, two somatic mutations were tested which were scored by 3DMTR as either tolerant (S64T) (Fig. 4C-4D) or intolerant (K89M) (Fig. 4E-4F). Wild type RGS10 and mutant proteins expressed well in HEK293 cells (Supp. Fig. 4B). The relative position of these residues within the RGS domain structure are shown in Fig. 4A highlighted as either red (tolerant) and blue (intolerant). Somatic mutations within the tolerant/intolerant residues of RGS10 exhibited phenotypes inconsistent with the 3DMTR prediction. Substituting a Thr for tolerant residue Ser64 (S64T) resulted in a partial LoF shown as a reduction in some, but not all capacity to inhibit receptor activation of G protein (Fig. 4C-4D). In contrast, substituting a Met for Lys (K89M) had no effect on RGS10 capacity to inhibit a2AR activation of Gαo (Fig. 4E-4F). Examining these results more closely, we find that residue K89 is located on an alpha helix away from the Gα binding interface, while S64 is located within the binding interface (Fig. 4A). This could explain why mutations at these sites resulted in the observed phenotype, though opposite of what would be expected from the 3DMTR prediction. However, we cannot rule of the possibility that substitution mutations to intolerant residue K89 may lead to other change of function.

We also measured direct RGS10 binding to active Gαo (Fig. 4B). Results showed that the mutant phenotypes matched the functional readouts for RGS10 regulation of receptor G activation. That is, mutant K89M bound active Gαo whereas mutant S64T did not. The fact that S64T showed some capacity to inhibit receptor-G activation but did not bind Gαo in the pull-down assay may reflect reduced affinity of this mutation for binding Gα. In summary, neither of
the two somatic mutations found in tolerant and intolerant residues of RGS10 as defined by 3DMTR behaved as predicted in this assay.

RGS4 belongs to the B/R4 subfamily of RGS proteins, it is a small structure composed of only the RGS domain and has been linked to many cancers by regulating cell proliferation and apoptosis (Xue et al. 2017; He et al. 2019; Park, Kim, and Moon 2017). It has also been associated with enhanced glioma cell motility, thyroid carcinoma, and ovarian cancer (Hurst, Mendpara, and Hooks 2009; Nikolova et al. 2008; Tatenhorst et al. 2004; Hurst and Hooks 2009). RGS4 has been linked to reduced protein expression in metastatic tumors in breast cancer migration (Xie et al. 2009), suggesting that RGS4 enhancement can potentially block invasion (Sjogren 2011). The relative position of selected somatic mutations on RGS4 are shown in Fig. 5A highlighted as either red (tolerant) and blue (intolerant). As with RGS14 and RGS10, we measured the effects of RGS4 on α2AR-directed Gao activation and direct RGS binding to Gao in cell lysates. For RGS4, three somatic mutations were tested which were scored by 3DMTR as either intolerant (K125Q and E126K) (Fig. 5C-5F) or tolerant (E135K) (Fig. 5G-5H). Unlike RGS14 and RGS10, wild type RGS4 failed to completely inhibit α2AR-directed Gao activation, as we’ve reported before (Brown, Lambert, and Hepler 2016). RGS4 inhibited Gao activation by approximately 75%. Intolerant mutants K125Q and E126K of RGS4 each exhibit partial loss-of-function phenotypes (Fig. 5C-5F), largely failing to inhibit Gao activation, whereas tolerant mutation E135K (Fig. 5G-5H) behaved as wild type RGS4.

We next examined the effects of somatic mutations on RGS4 capacity to bind directly to Gao (Fig. 5B). Mutants K125Q and E135K each bound active Gao, whereas mutant E126K did not bind. Intolerant mutant K125Q unexpectedly bound Gao. It should be noted that the LoF effects observed for K125Q mutation (Fig. 5D) are only partial, and that the protein may be able to bind without fully exerting GAP effects on Gao. RGS4 mutant E126K protein levels may be low in the cells (Supp. Fig. 4C), but sufficiently high enough to exert GAP effects of Gao.
3.4 The impact of somatic mutations on RGS protein regulation of intracellular cAMP levels

Findings to this point examined the impact of cancer somatic mutations on RGS protein regulation of receptor-directed G protein activation and G protein binding. The second messenger cAMP (3’-5’-cyclic adenosine monophosphate) is ubiquitously expressed and regulates cell proliferation and differentiation via PKA/Epac1 activation (Vitale et al. 2009). The cAMP-PKA signaling pathway has been linked to play roles in tumor biology. For example, in glioblastoma, increasing levels of cAMP inhibit cell growth by upregulating p21/p27 and PKA/Epac1-Rap1 signaling (Moon et al. 2012; Chen et al. 2002; Chen et al. 1998; Zhang et al. 2020). We next tested the effects of the cancer somatic mutations in key residues of RGS proteins downstream of G protein activation. For this, we examined the functions of cancer mutations of either a tolerant or an intolerant residue for each RGS protein (R173C and D137Y for RGS14, S64T and K89M for RGS10, and E126K and E135K for RGS4) in Gαi/o-inhibition of adenylyl cyclase stimulated cAMP accumulation (Fig. 6). The accumulation of cAMP in live cells was measured using the Luciferase-based GloSensor assay (Fig. 6A). Studies have shown RGS4 to regulate receptor and G protein-directed inhibition of AC (Huang et al. 1997), and RGS4 and RGS10 to inhibit forskolin stimulated cAMP production in CHOK1 cells stably expressing 5-HT1A receptor(Ghavami et al. 2004). However, the effect of RGS14, RGS10 and RGS4 effect on cAMP levels in cells expressing α2AR has not been explored. To measure RGS effects on receptor-Gαi/o inhibition of cellular cAMP, cells were stimulated first with α2AR-Gαi/o coupled agonist (100uM UK 14,304) or vehicle (DMSO), followed by forskolin (10uM FSK) to stimulate adenylyl cyclase (AC) production of cAMP (Fig. 6B). Of note, α2AR has been shown to couple to both Gs and Gαi/o in HEK cells (Wade et al. 1999). However, under the chosen experimental conditions, α2-AR-Gi/o coupling appears to dominate. That is, agonist activation of α2AR-Gαi/o significantly inhibited FSK-stimulated cAMP accumulation when compared to vehicle (Fig. 6C), indicating that FSK activation overrides any Gas contribution to cAMP.
formation. In each case, wild type RGS14, RGS10 and RGS4 reversed agonist-receptor-G protein inhibition of cAMP formation (Fig. 6D-F), with RGS14 being more effective than RGS10 and RGS4. Intolerant mutant R173C in RGS14 lost capacity to reverse G protein inhibition of cAMP, whereas tolerant mutant D137Y showed a robust capacity to enhance cAMP accumulation (Fig. 6D). Interestingly, tolerant mutation S64T in RGS10 acted like WT RGS10, opposite to the effects in receptor-directed G protein activation and G protein binding (Fig. 4B-4D), while intolerant mutant K89M showed a robust capacity to enhance cAMP accumulation (Fig. 6E). Intolerant mutant E126K in RGS4 lost the capacity to reverse G-protein inhibition of cAMP, while tolerant mutant E135K acted like RGS4 WT (Fig. 6F). The same trends were observed here as was for receptor-directed G protein activation and G protein binding (Fig. 5B and 5E-5H).

Several studies have identified RGS proteins to be regulators of adenylyl cyclase (AC) activity. RGS2 decreases accumulation of cAMP by directly interacting with type V AC (Salim et al. 2003; Roy et al. 2006), and RGS4 and RGS10 inhibited G-protein-independent cAMP production in CHOK1 cells (Ghavami et al. 2004). However, the actions of RGS14 on AC activity has not been explored. Therefore, we next examined the effect of RGS proteins on forskolin-stimulated cAMP production directly, in the absence of agonist-activated α2AR-G protein contributions (Fig. 7A). Results for WT RGS14, RGS10 and RGS4 (Fig. 7B-7D) did not show an inhibition of FSK-stimulated cAMP levels in HEK293 cells transfected with α2-AR without agonist stimulation. Tolerant mutant D137Y in RGS14 showed a robust increase in cAMP levels in the absence of agonist-stimulated Gi/o-coupled receptor (Fig. 7B). Interestingly, tolerant mutant S64T in RGS10 showed an increase in cAMP levels when compared to WT RGS10 that had no effect (Fig. 7C). This trend is the opposite of the results shown in the previous assay of RGS10 mutant effects on receptor inhibition of cAMP (Fig. 6E). Mutations in E126K and E135K of RGS4 showed similar results to the effects shown for WT RGS4 (Fig. 6F).
4. Discussion

4.1 3DMTR analysis is a more accurate predictor than 1DMTR

In the present study, we performed a functional assessment of the predictive capabilities of the novel 3DMTR analysis applied to RGS proteins. The MTR method analyzes the regional intolerance to mutations in proteins of interest (Traynelis et al. 2017). Recent efforts have refined this tool and improved its predictive qualities (Perszyk et al. 2021). Using the 3D protein structure allows for a more refined and accurate prediction of important protein regions as it is common for non-adjacent segments of the polypeptide chain to come together in the tertiary and quaternary structure of a protein. We were able to identify important residues that show intolerance to genetic variance in most RGS domains of the RGS analogs that had a reported protein structure (Supp. Fig. 1-2). Our results show that the 3DMTR analysis is a more accurate predictor of regional intolerance when compared to its 1DMTR (Table 2). When we compared against the predictive qualities of other bioinformatic tools (SIFT, PROVEAN, MutPRED2; Supp. Tables 2-4), 3DMTR was the most accurate at predicting intolerant residues of the protein that, if mutated, would lead to deleterious effects and change-of-function phenotypes. All nine selected residues in RGS14, RGS10 and RSG4 were predicted to be tolerant to change by the 1DMTR, while the 3DMTR predicted five of nine to be intolerant to change. The 3DMTR identified intolerant and tolerant mutated residues affected in GPCR-G protein activation and G protein binding. For RGS14, three of four, and three of three for RGS4 matched the 3DMTR-permutaiton analysis predictions. RGS10 mutants gave results that were opposite of expected in GPCR-G protein activation and G protein binding assessments.

While greatly improved over the 1DMTR, the 3DMTR analysis was not perfect in its predictive power, with discrepancies noted after some functional assessments. The function of an RGS protein in GPCR-G protein activation and G protein binding is dependent on residue
selectivity (Xie and Palmer 2007). When the mutations examined here were tested downstream of the GPCR for RGS14 and RGS4 (e.g., cAMP accumulation), the intolerant and tolerant mutants behaved as expected in most, but not all cases. For example, the tolerant residue D137Y in RGS14 presented as tolerant in the Ga coupling assay, but showed an unexpected enhanced gain-of-function effect in the cAMP assay. Another example of a mutant with a conflicting phenotype was intolerant residue K89M in RGS10. We found that K89M was tolerant and behaved as wild type protein in the G protein coupling assay but exhibited altered function in the assessment of inhibition of Gi/o-inhibition of cAMP levels causing an enhanced activity. In both cases, the cAMP assay measures adenylyl cyclase (AC) activity, and it should be noted that some RGS proteins bind directly to certain AC isoforms to stimulate their activity (Salim et al. 2003; Roy et al. 2006). In this case, tolerant D137Y RGS14 mutant and intolerant K89M RGS10 mutants could interact directly with AC, or the AC-Ga complex, to stimulate AC enzyme activity. Consistent with this idea, our findings in Figure 7 indicate enhanced AC activity with these mutants in the absence of receptor agonist. Alternatively, the functional assessment of these assays relies on the network of residues that make direct contact with the active Ga. The intolerant K89M mutation is found away from the binding site in RGS10, and this could explain why it did not lead to an altered loss-of-function phenotype in G protein coupling but did exhibit a phenotype in the cAMP assay. As a tangential side note, RGS actions on AC have not been extensively studied. Our observations of RGS mutant effects on forskolin-stimulated AC raises the question of whether RGS proteins in general regulate AC differently with forskolin vs GPCR-Gs-activation, a topic for future study.

Despite these examples, the 3DMTR was a good overall predictor of intolerant residues that resulted in a change-of-function. The 3DMTR results need to be placed in perspective compared with other available tools, that are demonstrably less accurate predictors of change-of-function. For example, and as noted above, the COSMIC-FATHMM-MKL algorithm inexplicably designated silent mutations in residues N93, A99 and R173 of RGS14 to be
pathogenic which, of course, is not possible at the protein level. In the future, the 3DMTR may also develop into a more precise tool. Specifically, as the Genome Aggregation Database (gnomAD) source data for the method collects more human synonymous and missense variant information, the analysis may be more accurate and/or require fewer residues to aggregate data that may lead to improved predictive potential.

4.2 RGS proteins in cancer and the impact of linked mutations in signaling pathways

Roles for RGS proteins in GPCR-G protein signaling in human cancer have not been extensively studied, though genetic variants in RGS proteins linked to cancer have been reported (Dai et al. 2011; Lee et al. 2013; Qutob et al. 2018; DiGiacomo et al. 2020). GPCRs have been shown to play a role in the initiation and progression of cancer, suggesting that regulators of GPCRs are also important in regulating oncogenic pathways. However, the specific roles of RGS proteins in regulating oncogenic pathways are still being studied.

In this study, we examined cancer associated mutations in RGS proteins that overlap with the significant residues identified by 3DMTR analysis. Of note, most cancer-linked mutations in RGS proteins have not been tested, except for a recent report (DiGiacomo et al. 2020). Here we tested nine cancer-linked mutations across three different RGS proteins for their functional phenotypes. These nine mutants were tested because they overlapped with residues predicted by 3DMTR to be either tolerant or intolerant to change and were predicted by the FATHMM analysis to have deleterious effect in protein function. These cancer-linked mutations were tested for their capacity to impact GPCR-G protein signaling. GPCR signaling can be altered by aberrant receptor overexpression, gain-of-function activating receptor, or mutations in downstream G protein signaling effectors, like RGS proteins, that favor oncogenicity (Gutkind 1998). A recent study has identified 475 mutations reported in the RGS domain of RGS proteins present in 22 cancer types (DiGiacomo et al. 2020). We explored the functional effects that cancer associated mutants have in regulating RGS-G protein activation and downstream
effector signaling. Eight out of the nine tested mutants led to a change-of-function phenotype. Tightly regulated GPCR-G protein-RGS signaling pathways control many important physiological events. GPCRs show selectivity to Ga-subtypes as well as RGS proteins (Xie and Palmer 2007), and activate/regulate specific downstream second messenger signaling pathways (e.g. cAMP) to mediate cell migration and survival (O’Hayre, Degese, and Gutkind 2014). Mutations in RGS proteins can lead to GPCR signaling dysregulation, which has been linked to roles in certain cancers (Arang and Gutkind 2020; DiGiacomo et al. 2020). Loss-of-function mutations in RGS proteins, like RGS14-R173C/H and RGS4-E126K/K125Q, could increase G protein activity serving to promote tumor growth mechanisms (Nishihara et al. 2004). Likewise, RGS genetic variations also could be associated with patient response to chemotherapies that specifically target GPCRs (Dai et al. 2011).

Recent advances in genome technology have allowed for a better understanding of the contribution of intolerant genetic variants in cancer pathogenesis. This, in turn, has allowed for improved diagnosis, and improved selection of cancer treatments in personalized medicine. Tools such as the novel 3DMTR analysis could enable biomedical researchers to prioritize which mutations/residues should be tested first for studying change-of-function phenotypes. Examples of this approach in other disease states such as idiopathic epilepsy have yielded remarkably promising results (Perszyk et al. 2021; Epi 2015). Because bioinformatic tools are not perfect, the major challenge will be to make biological sense of data from large publicly available disease-linked genetic data bases and computational analysis. Our small-scale project is an example of how using the correct bioinformatic tools and testing that tool’s predictive capabilities can elucidate the role of understudied genetic variants in RGS and other proteins in cancer disease progression.

(C) The MTR score of RGS14 taking into consideration three-dimensional space (3DMTR). Green squares represent a synonymous variant in that residue. Orange squares represent missense variant for the residue. Below is a linear heatmap of the MTR score for RGS14. (D) Structural view of RGS14 3DMTR raster plot scores. (E) Scatter plot of RGS14 3DMTR score (magenta line), permutation analysis score mean (black line), and 2x standard deviation around the permutation score mean of the permutation analysis (gray areas). (F) Structural view of the permutation analysis raster plot significantly intolerant residues within RGS14.

**Figure 2. The 3DMTR permutation analysis identifies significantly intolerant residues within the RGS domain that were not identified by 1DMTR.**

(A-C) Raster plot of selected RGS proteins comparing 1DMTR, 3DMTR based on the 31 neighboring residues, 3DMTR based on the 21 neighboring residues, and significantly intolerant residues based on the permutation analysis (rows labeled “c21-sig.”, labeled by a blue rectangle). (D-F) Structural views of RGS domains colored to show a heatmap of the 21-residue 3DMTR score (intolerant residues in blue, neutral in white, tolerant in red) bound to G alpha. (G-I) Structural view of the 21-residue 3DMTR permutation analysis raster plot significantly tolerant/intolerant residues. (J) RGS protein alignment shows the RGS domain (lilac), residues in the hydrophobic core (yellow), residues in direct contact with G alpha (grey), and selected residues to test the functional consequences inside box. The residues with a 3DMTR score >0.5 are determined to be not highly intolerant (tolerant) and the color letter is red. Residues with a 3DMTR score ≤0.5 are determined to be highly intolerant and the color...
letter is blue. Residues identified via the permutation analysis are identified with symbols * (MTR ≤ 0.5, highly intolerant) or ^ (MTR > 0.5, not highly tolerant).

**Fig 3** Assessment of functional impact of RGS14 somatic mutations on GPCR-G protein activation and G protein binding. (A) Schematic representation of kinetic BRET experiments. HEK 293 cells were transfected with 200 ng of α2A-AR, 200 ng of Venus-Gβ1 200 ng of Venus-Gγ2, 200ng of mas-GRK3ct-Luc, 1000 ng of mutant Gαo (PTX insensitive), and 0 or 200ng of WT Flag-RGS or 200ng of Flag tagged RGS mutant. (B) Structural view of selected mutated tolerant (red) and intolerant (blue) residues in RGS14. Average whole traces of BRET signal over time (n = 3) are shown comparing WT and somatic mutations. 3DMTR identified residues that led to loss of function are tolerant residues Flag-S127P (C), and intolerant mutated residues Flag-R173C (G) and Flag-R173H (I). Tolerant residue Flag-D137Y (E) did not lead to change of function. BRET amplitude observed at 100s was compared between 0ng RGS14, 200ng WT RGS14, and mutants Flag-S127P (D), Flag-D137Y (F), Flag-R173C (H), and Flag-R173H (J). Error bars represent mean +/- S.D. Statistical analysis was performed using one-way ANOVA with Dunnett’s test (**P < 0.005). (K) Co-immunoprecipitation studies show that RGS14 mutants S127P, R173C and R173H blocked binding to Gao-AlF4

**Fig 4.** Assessment of functional impact of RGS10 somatic mutations on GPCR-G protein activation and G protein binding. (A) Structural view of selected mutated tolerant (red) and intolerant (blue) residues in RGS10. (B) Co-immunoprecipitation studies show that mutants K89M bound to Gao-AlF4 while S64T blocked binding. Average whole traces of BRET signal over time (n = 3) are shown comparing WT and 3DMTR somatic mutations in identified tolerant residue Flag-S64T (C) and intolerant residues Flag-K89M (E). BRET amplitude observed from data presented for Flag-S64T (D) and Flag-K89M comparison (F). Tolerant residue Flag-S64T (C-D) led to change of function while intolerant Flag-K89M (E-F) did not change. Error bars
represent mean +/- S.D. Statistical analysis was performed using one-way ANOVA with Dunnett’s test (**P < 0.005).

**Fig 5. Assessment of functional impact of RGS4 somatic mutations on GPCR-G protein activation and G protein binding.** (A) Structural view of selected mutated tolerant (red) and intolerant (blue) residues in RGS4. (B) Co-immunoprecipitation studies show that RGS4 WT, K125Q and E135K mutants bound Gao-AlF4-. Average whole traces of BRET signal over time (n = 3) are shown comparing WT and 3DMTR identified tolerant and intolerant residues HA-K125Q (C), HA-E126K (E) and HA-E135K (F). BRET amplitude at 100s observed from data presented for HA-K125Q (D), HA-E126K (F) and HA-E135K (G) comparison. Intolerant mutants HA-K125Q (C-D), HA-E126K (E-F) led to loss of function phenotypes while tolerant HA-E135K (G-H) did not. Error bars represent mean +/- S.D. Statistical analysis was performed using one-way ANOVA with Dunnett’s test (**P<0.0005, **P < 0.005, *P<0.05).

**Fig 6. Assessment of functional impact of wild type vs mutant forms of RGS14, RGS10 and RGS4 on a2A-AR-G protein directed inhibition of cAMP levels.** HEK293 cells were transfected with constructs encoding gloSensor cAMP reporter, a2A-AR, and RGS proteins of interest. At time 0, cells were treated with vehicle (◇ DMSO) or agonist (● 100μM of UK 14,304). After a 10 min incubation at RT, cells were stimulated with FSK (10μM). Luminescence intensity indicative of cAMP production was measured every 5 minutes for up to 50 minutes at room temperature. Values shown in each time-course panel are means of triplicates from individual experiments, representative of 3-4 independent experiments. Data shown as +/- SD, n=3-4 independent experiments represent the relative luminescence intensity AUC (Area under the curve). (A) Schematic representation of the gloSensor.cAMP reporter, and (B) schematic representation of the assay design. (C) In the absence of RGS proteins, FSK alone increases
cAMP levels while agonist-Gai/o stimulation leads to a significant decrease in cAMP. Bar graph shows comparative data values of AUC. (D) RGS14 WT compared to mutants resulted in significantly different cAMP levels over time. Bar graph shows comparative data values of AUC. (E) Comparison between RGS10 and mutants did not lead to any significant differences. Bar graph shows comparative data values of AUC. (F) Comparison between RGS4 and mutants did not lead to any significant differences. Bar graph shows comparative data values of AUC. Statistical analysis was performed measuring the AUC, using unpaired t test for C, and one-way ANOVA and Dunnett’s multiple comparison test for D-F (*p<0.05, **p<0.005).

Fig 7. Assessment of the functional impact of wild type vs mutant forms of RGS14, RGS10 and RGS4 on FSK-stimulated cAMP production by adenylyl cyclase (AC). HEK293 cells were transfected with constructs encoding gloSensor cAMP reporter, a2A-AR, and RGS proteins of interest. At time 0, cells were treated with vehicle (DMSO) and after a 10 min incubation at RT, cells were stimulated with FSK (10μM). Luminescence intensity indicative of cAMP production was measured every 5 minutes for 50 minutes at room temperature. Values shown in each time-course panel are means of triplicates from individual experiments, representative of 3-4 independent experiments. Data shown as +/- SD, n=3-4 independent experiments represent the relative luminescence intensity AUC. (A) Schematic representation of the assay measuring the effects of RGS proteins in AC stimulated cAMP. (B) RGS14-D137Y led to a significant increase in AC stimulated cAMP levels compared to WT and other mutants. Bar graph shows comparative data values of AUC. (C) RGS10-S64T led to a significant increase in AC stimulated cAMP levels compared to WT and other mutants. Bar graph shows comparative data values of AUC. (D) There was no significant difference between RGS4 WT and mutants. Bar graph shows comparative data values of AUC. Statistical analysis was performed measuring the AUC and analyzing the difference between the conditions using one-way ANOVA and Dunnett’s multiple comparison test (*p<0.05).
Table 1. Tolerant and intolerant residues from RGS domains of interest that also overlap with highly deleterious somatic mutations were selected for assessment of their impact on RGS functions.

Amino acids reported in the COSMIC cancer database were selected based on the criteria that were predicted to be pathogenic by the FATHMM score to be highly pathogenic. Scores above 0.5 are deleterious, scores ≥0.7 are classified as pathogenic.

Summary results of the multiple functional assessments performed to characterize the effects of the reported mutations. Overall, the 3DMTR analysis is a better predictor of intolerant protein regions than 1DMTR. With this information we can better predict which reported mutations will lead to a change-of-function phenotype.
